Normally, there is negligible release of radioactive materials from a properly operating nuclear power plant. Releases that are of concern occur during accidents. In October of 1957, a fire at the reactor at Windscale in the UK led to the release of an estimated 600 TBq of I-131, 45 TBq of Cs-137 and 0.2 TBq of Sr-90 (Crick and Linsley, 1984). On March 28, 1979, the reactor at the power plant on Three Mile Island near Harrisburg, Pennsylvania, experienced a partial meltdown before the situation could be brought under control. Only small amounts of radioactivity were released. On April 26, 1986, there was a catastrophic accident at the Chernobyl power plant in Ukraine. There were 31 deaths caused by the accident, 28 of which were attributed to acute radiation syndrome. An estimated 260,000 TBq of I-131, 38,000 TBq of Cs-137 and 8000 TBq of Sr-90 were released along with a large amount of other radioactive materials. Cs-137 and Sr-90 are of concern because of their relatively long  $t_{1/2}$  of 30.0 and 29.2 years, respectively. Although I-131 has a short  $t_{1/2}$  of just over 8 days, it is concentrated by the thyroid, increasing the likelihood of acute tissue damage or latent effects. This is exemplified by the fact that 14 years after the Chernobyl accident the only prevalent disease was thyroid cancer in children with about 700 cases being reported.

At 2:46 pm local time on March 11, 2011, a magnitude 8.9 earthquake centered just off the northeast coast of Japan generated a tsunami that came ashore moments later. The earthquake and ensuing tsunami damaged the Fukushima Dai-ichi nuclear power plant and disrupted the power needed to cool the reactor. The situation is ongoing and the level on the International Nuclear and Radiological Event Scale (INES) established in 1990 by the International Atomic Energy Agency (IAEA) remains

at 7 – the highest level. Thus far, there have been no casualties though some workers were exposed to radiation and the accident led to the evacuation of residents within a 20 km radius of the plant. It has been estimated that the release of radioactivity is about 1/10th of what occurred at Chernobyl.

### Sterilization of food products

Radiation has been used since the 1950s to sterilize food products. A source of gamma rays such as Co-60 or Cs-137 is used for the purpose though ultraviolet radiation is preferred for some foods, milk being an example, because its flavor is changed by gamma rays. Typically, the dose of gamma rays is 5–10 kGy and there is no contamination of the food by the radioactive source because it never comes into contact with the food. Keep in mind that the food itself will naturally contain small amounts of radioactive materials, primarily K-40 and C-14. The use of radiation is an effective way of destroying pathogens like *Salmonella* bacteria. As has been discussed, ionizing radiation by its nature has the ability to cause chemical changes in the materials that it comes into contact with and the fact that the flavor of milk is altered by gamma rays attests to this fact. However, studies have shown that the doses of radiation used for treating foods causes minor chemical changes that are not harmful to humans. It is appropriate to point out that other methods of food preservation including heating and the addition of chemical preservatives also cause chemical changes in the food. One advantage of using radiation for food preservation is that it often does a superior job of protecting food quality compared with other methods of sterilization.

### Medical diagnostics and treatments

Radiation has been used for more than 50 years to sterilize certain medical equipment and supplies, bandages for example, that are not amenable to sterilization by high temperature steam in an autoclave. Sterilization is achieved by exposure to gamma rays from a Co-60 source that delivers doses of 20–40 kGy. Using radiation to sterilize equipment and supplies does not expose patients or health care workers to radiation unless there is an accident like the one that occurred in Norway in September of 1982. The failure of a safety lock and warning system coupled with a failure to follow safety procedures resulted in a worker being exposed to a Co-60 source that was used to sterilize medical equipment. The accident resulted in the worker's death 13 days later. At the time of the accident, the consequences of exposure to high levels of radiation were well known. This was not

the case when X-rays were discovered and their use as a diagnostic tool in medicine was beginning to be used. As a result, physicians were exposed to an occupational hazard that they were not aware of. A number of doctors using X-rays daily developed squamous cell carcinomas on their hands and arms. Once a connection was made between X-ray exposure and cancer, steps were taken to protect health care workers and the problem was essentially eliminated.

Patients receive exposure to ionizing radiation when undergoing certain medical diagnostic procedures. The largest increase in exposure to ionizing radiation in the last few decades has come from medical X-rays. According to the National Council on Radiation Protection and Measurement, exposure to radiation for medical purposes has increased from 18% of the total annual exposure in the early 1980s to 48% in 2006 (Table 25.8). The majority of the increase is attributable to X-rays received from diagnostic computer tomography (CT) scans. CT scans represent an important advance in diagnostic procedures, but it requires much larger doses of radiation than conventional X-rays taken with film (Table 25.9). Unlike occupational exposure, medical exposure is not well regulated. A patient might see several different physicians during the year, and each might prescribe a CT scan, resulting in a significant increase in the annual exposure. The increase in exposure to medical X-rays has raised concerns about an increase in the risk of cancer occurring as a latent effect (Brenner, 2007).

Patients are also exposed to radiation for therapeutic purposes. It may seem somewhat ironic to be treating cancer with doses of radiation that can increase one's risk of developing the disease, but it is a matter of risk versus benefit. Fast-growing cells such as tumor cells are more susceptible to being killed by radiation than are normal quiescent cells. Nonetheless, non-cancerous cells are damaged by radiation and therapeutic treatments must be designed to effectively destroy tumor cells while having a minimal impact on normal cells.

### Dose–response curves for accessing risk

There are basically two models that correlate dose versus risk. One presumes that there is a linear relationship between dose and risk with no threshold that must be crossed before a risk exists (curve a in Figure 25.4). This is known as the linear no threshold (LNT) model. The other model posits that below a certain threshold there is no increase in risk with dose but, once the threshold is reached, the risk increases in proportion to the dose (curve b in Figure 25.4). A variation on the latter model (Luckey, 2003) proposed that below the threshold there may be doses of radiation that are beneficial in that these may stimulate or prime the processes within the

**TABLE 25.8** Changes in the annual dose of radiation received by individuals from 1980 to 2006 according to the UNSCEAR 2008 Report to the General Assembly with Scientific Annexes, p. 33

Source	Annual dose in mSv	
	1980	2006
Natural sources	2.4	3.1
All medical sources	0.53	3.0
All other sources	0.05	0.14

**TABLE 25.9** Typical doses of radiation received from medical diagnostic X-rays

Source of X-ray	Dose
<b>Conventional X-rays</b>	
Dental	0.005 mSv
Chest	0.01 mSv
Lateral chest	0.15 mSv
<b>CT scans</b>	
Head	2 mSv
Chest	10 mSv
Abdomen/pelvis	10 mSv
Extremity (hand/foot)	0.1 mSv
Spine	10 mSv
Whole body	10 mSv
Cardiac	20 mSv

cell that are responsible for repairing damage caused by radiation or chemical insults (curve c in Figure 25.4). This phenomenon of priming the repair mechanisms is also known as an “adaptive response” and the beneficial effects are known as radiation hormesis.

The conservative approach is to adopt the LNT model when developing policy to protect individuals from the effects of radiation. However, there are data suggesting that the second model gives a more accurate picture of the situation. Consider the plight of radium dial painters. In the early 1900s, women were employed to paint the hands and dials of clocks and watches with radium paint. The paint contained a mixture of radium radioisotopes and radioluminescent zinc sulfide crystals. As radium decays, it transitions from one radioactive element to another by a series of alpha and beta particle emissions, converting it to a stable isotope of lead. These ionizing particles excite electrons in the zinc sulfide and the electrons emit a photon of visible light when they lose this excess energy. As discussed earlier, most alpha and beta particles emitted by radioactive materials are not very penetrating and can be easily stopped by the glass covering of a watch or in the case of alpha particles by clothing or a few layers of skin cells. However, when ingested or inhaled the source of alpha and beta particles cause damage to the cells they come into contact with. Radium dial painters would tip their paint brushes with their lips to shape them for doing the delicate work at hand and, in so

**FIGURE 25.4** Hypothetical dose-response curves for (a) linear no threshold (LNT) response model, (b) threshold model where risk is not increased at low doses of radiation and (c) a model in which low doses of radiation reduce the risk of diseases (radiation hormesis) until a threshold is crossed where increasing dose correlates with increasing risk of developing cancer.

doing, ingested radium. Radium is primarily deposited in bone and many of the women developed bone carcinomas and anemia from radium’s effect on the bone marrow. One hundred and twenty women are known to have died as a result of ingesting radium paint. Once cause and effect was established, a warning was issued to dial painters not to tip their brushes with their lips. Although radium dial painting continued, no dial painter who began work after 1925 when the warning was issued, has been diagnosed with cancer. Nonetheless, dial painters acquired a radioactive burden as can be seen from Figure 25.5 (Rowland and Lucas, 1983) but at a reduced level compared with those women who started painting before 1925. This suggests that there is a dose threshold that must be crossed before there is an increase in the risk of developing cancer. Similar results have been observed in experimental protocols.

Studies have been conducted to evaluate the effects of acute exposure to radiation on the health of individuals living in Hiroshima and Nagasaki, at the time the nuclear bombs were dropped. The combined population of these two cities in August of 1945 was estimated to be 429,000, and 103,000 were killed outright or died within the first 4 months following the blasts. In 1950, there were 283,000 individuals who claimed to have been exposed to radiation from the bombs. A group of these individuals was selected to take place in a Life Span Study Cohort that will continue until 2015. Results obtained thus far suggest that acute effective doses of less than 100 mSv do not increase the risk of developing cancer.

There is accumulating evidence that low levels of radiation can have hormetic effects (Johansson, 2003; Jolly

**FIGURE 25.5** The dose measured as systemic intake in  $\mu\text{Ci}$  (see Tables 25.2 and 25.4 for conversion of  $\mu\text{Ci}$  to Bq) is plotted against the years in which the dial painters began work. The original figure is reproduced here with a horizontal line at  $40 \mu\text{Ci}$  added to indicate the dose below which no dial painters had developed cancer by the time of the report in 1983. Systemic intake is defined as  $\mu\text{Ci}$  of R-226 +  $2.5 \times \mu\text{Ci}$  of R-228. For additional information see Rowland and Lucas (1983). The original report is available at <http://www.osti.gov/bridge/servlets/purl/6374911-rHt6M2/>

and Meyer, 2009). When thymidine is added to the culture medium, lymphocytes will incorporate it into their DNA. If tritium (H-3) is substituted for hydrogen atoms in thymidine, the DNA will be radioactive exposing the cells to low levels of beta radiation. The cells were then exposed to 1.5Gy of X-rays and the extent of chromosomal aberrations determined. Cells that incorporated tritiated thymidine had fewer chromosomal aberrations than did control cells grown in thymidine that was not radioactive, suggesting that a low level of chronic exposure to radiation evokes an adaptive response that protects cells from the effects of subsequent high doses of radiation (Olivieri *et al.*, 1984). Blocking protein synthesis blocked the protective effects of low doses of radiation providing evidence that the mechanism of protection involved inducing protein synthesis, and the evidence suggests that this includes the enzymes that are important for DNA repair. Experimental paradigms analogous to those used to study adaptive response in cultured cells have also been used to investigate the phenomenon in whole organisms like fruit flies (Moskalev *et al.*, 2009) and mice (Mitchel *et al.*, 1999) with similar results. *In vivo* studies indicate that irradiation of mice at a rate 25–50

times the normal background significantly increase lifespan (Caratero *et al.*, 1998), immune competency (Ina and Sakai, 2005) and latency in the onset of spontaneously occurring and induced tumors (Mitchel *et al.*, 2003; Cheda *et al.*, 2004). If the dose of radiation is low enough, no beneficial effects can be demonstrated suggesting that there is a threshold for hormesis (Elmore *et al.*, 2008; Mitchel *et al.*, 2008). In addition to dose, the dose rate and the length of exposure are likely to be important factors in hormesis. Another point to consider is whether different types of cancer have different thresholds for both hormesis and risk.

### Current recommendations regarding exposure limits

Despite the forgoing discussion, studies indicating that low doses of radiation are not detrimental and likely beneficial have not been unequivocally established. Consequently, agencies charged with issuing recommendations and policies regarding radiation exposure such as the International Commission on Radiological Protections (ICRP) and the United Nations Subcommittee on the Effects of Atomic Radiation (UNSCEAR) assume that the LNT model applies. Based on this model, the recommendation is that exposure to ionizing radiation beyond background should be kept “as low as reasonably achievable” (ALARA). The current recommendations on exposure limits are different for those who experience occupational exposure and the general public. The recommendation of the ICRP is that the dose to radiation workers for a 5-year period should not exceed 100 mSv, and no more than 50 mSv should be received in a single year. For radiation workers who become pregnant, the dose to the fetus should be kept below 1 mSv between the time pregnancy is confirmed and the fetus reaches term. The annual dose to the general public should not exceed 1 mSv above the dose from background radiation. In light of accumulating data suggesting that low levels of radiation may not be harmful, and may even be beneficial, the currently recommended limits may need to be revised.

## CONCLUSIONS

Ionizing radiation is a double-edged sword. Released by nuclear weapons it can result in an agonizing death within days, weeks or years of exposure. But ionizing radiation has been a fact of life ever since it evolved on earth more than 3 billion years ago. Although an

appreciation of the potentially devastating effects of radiation arose in the early 20th century with the plight of the radium dial workers, widespread fear of radiation was not established until nuclear weapons were used to destroy Hiroshima and Nagasaki in 1945. Today, the choices we make with regard to the use of radiation require careful consideration. For example, nuclear power carries with it risk that has been made obvious by the accidents at Windscale, Three Mile Island, Chernobyl and Fukushima Dai-ichi, but the human deaths and environmental destruction that have resulted from the use of nuclear power are far less than that associated with the coal industry. In a time when carbon dioxide produced by the burning of fossil fuels is generally accepted as the primary cause of global warming with its potentially disastrous environmental consequences, the ability of nuclear reactors to generate power without producing carbon dioxide makes it an attractive alternative. Today, decisions about radiation extend to the individual choices we make as well. More than ever before, medical diagnostic procedures rely on radiation-based techniques. There are currently no regulations regarding tracking or limiting the total annual exposure received by patients. To an extent, the obligation falls on the individual to weigh risk and benefit. This requires keeping track of exposure and knowledge of safe dose limits. The uncertainty discussed earlier with regard to those limits makes the decision more difficult.

# Carcinogenesis: mechanisms and models<sup>1</sup>

*Supratim Choudhuri, Kirk Arvidson and Ronald Chanderbhan*

## INTRODUCTION

Animals, like humans, have always been exposed to thousands of chemical substances in their daily lives. This exposure may come from the food they eat, the water they drink and the air they breathe. A high level of exposure to many of these chemicals may cause cancer in humans and animals.

Cancer has become an increasingly prominent disease in recent times but the incidence of cancer had been documented through writings and drawings thousands of years ago. The earliest known descriptions of cancer were found from the writings in Egyptian papyri, discovered and deciphered in the late 19th century. Two of these papyri, which were written around 1600 BC and called "Edwin Smith" and "George Ebers" papyri, contain descriptions of various cancers and Egyptian medical practice of treating cancer. Hippocrates is credited with naming cancer as *karkinoma* (carcinoma) because a tumor looked like a "crab" (*karkinoma* is Greek for crab). Hippocrates believed that the body contained four types of "humors" (body fluids): blood, phlegm, yellow bile and black bile. An excess of black bile collecting in various body sites was thought to cause cancer. The black bile theory of cancer was supported by the influential Greek physician Galen and it dominated scientific thought for over 1300 years. The black bile theory of cancer was eventually replaced by the lymph theory of cancer in the 17th century. The lymph theory was developed from the discovery

of the lymphatic system by the Italian surgeon Gaspare Aselli, and abnormalities of lymph were viewed as the primary cause of cancer. Eventually, the lymph theory gained rapid support. The Scottish surgeon John Hunter (1723–1792) lent support to the lymph theory by hypothesizing that tumors grew from lymph that is constantly thrown out by the blood. It took another 100 years or so before the cellular basis of cancer could be contemplated. The cellular origin of cancer was propounded by Rudolph Virchow in the late 19th century when he recognized that cells, even cancerous cells, were derived from other cells.

In keeping with the theories on the possible physiological causes of cancer, an increasing number of reports from Europe and England documented the association between occupation/chemical exposure and the development of cancer. For example, Paracelsus was probably the first to identify a chemical substance, arsenic disulfide, as the causative agent of lung cancer in the miners of Schneeberg and Joachimsthal, Germany. In 1713, the Italian physician Bernadrino Ramazzini reported the absence of cervical cancer and higher incidence of breast cancer in nuns and thought this was related to their celibacy. The English physician Percival Pott observed that young men in their twenties who had been chimney sweeps had a high rate of cancer of the scrotum. He suggested that the causative agent might be chimney soot (tar) and recommended frequent washing and changing of clothes in order to reduce exposure to the soot. John Hill (1761) in the U.K. implicated the use of tobacco as snuff in the development of nasal polyps. In 1795, Samuel Thomas von Soemmering in Germany reported the occurrence of lip cancer among pipe smokers. In 1895, Ludwig Wilhelm Carl Rehn reported the occurrence of bladder cancer among workers in the

<sup>1</sup>The opinions expressed in this article are the authors' personal opinion and they do not necessarily reflect those of FDA, DHHS or the federal government.

German dye industry. Various epidemiological studies have since identified major environmental causes of cancer, which include both naturally occurring chemicals as well as man-made chemicals.

Experimental cancer research began in the early 20th century and has been continuing since. Recent advances in molecular genetics have provided researchers with additional tools to study the mechanisms and the molecular biology of cancer. The knowledge gained from such studies form the foundation of our understanding of the process of carcinogenesis. Today, chemical carcinogenesis is regarded as a multistep process with a long latency period. For a relatively detailed historical perspective of cancer, readers are referred to [Marquardt \(1999\)](#), [Pitot \(2002\)](#) and the American Cancer Society website.

## TERMINOLOGY

*Cancer* is a term that is commonly used to indicate a group of diseases characterized by uncontrolled cell proliferation and usually the spread of these abnormal cells. In common parlance, the word cancer is near-synonymous with other expressions such as *malignant tumor*, *malignant neoplasm*, *malignancy* and *neoplasia*. Tumors or neoplasms (new growth of tissue) can thus be benign or malignant (cancerous). In this chapter, these expressions will be used interchangeably. Agents causing cancer are called *carcinogens* and the process of cancer development is called *carcinogenesis*. Most neoplasms arise from the clonal expansion of a single cell that has undergone neoplastic transformation. Hence, cancers are monoclonal. According to [Pitot \(2002\)](#), *neoplasia* or the constituent lesion *neoplasm*, can be defined as a heritably altered, relatively autonomous growth of tissue. The “heritably altered” aspect reflects the abnormal genetic expression, which is either inherent in the neoplastic cells or is induced in response to environmental stimuli. Another term relevant to cancer is hyperplasia. *Hyperplasia* means an increase in cell number. Hyperplasia can be found in neoplastic as well as non-neoplastic conditions. Examples of non-neoplastic hyperplasia include callus formation, hepatomegaly (liver enlargement), etc. Hepatomegaly in response to various xenobiotic treatments usually involves both hyperplasia and hypertrophy (enlargement of cells).

In the parlance of cancer biology, the suffix “oma” means tumor, benign or malignant. For example, *fibroma* and *lipoma* are benign neoplasms, while *melanoma*, *hepatoma* and *seminoma* are malignant neoplasms. Sometimes even non-neoplastic lesions end with the “oma” suffix, such as *hematoma* and *granuloma*. A hematoma is a localized collection of blood outside the blood vessels, usually in liquid form within the tissue. This happens when blood escapes

into the surrounding tissue because of damage to the blood vessels. Likewise, a granuloma is a small patch of inflamed tissue that results from infection or inflammation. Cancer of the embryonic tissue is denoted with the suffix “blastoma,” such as *neuroblastoma* and *retinoblastoma*. Similarly, cancer of connective tissue, such as bone, cartilage, fat, muscle and blood vessels, is denoted with the suffix “sarcoma,” such as *fibrosarcoma*, *liposarcoma* and *rhabdomyosarcoma*.

## CANCER EPIDEMIOLOGY

Cancer incidence data are available in many countries from registries that monitor the occurrence of different types of cancers in various populations. Epidemiological data show that certain cancers tend to occur more frequently among people in certain geographic locations. For example, breast and prostate cancers have lower incidence rates in Asian countries but higher incidence rates in Europe and North America ([Haas and Sakr, 1997](#); [McPherson et al., 2000](#)). In contrast, gastric cancer has lower incidence rate in economically developed western countries including the U.S., but higher incidence in Japan and Korea ([Alberts et al., 2003](#)). These differences in cancer incidence reflect the role of both genetic and environmental factors. Strong evidence for the importance of environmental factors comes from studies on migrant populations. When there is a significant difference in the incidence of a specific cancer in the native country and the new host country, the migrant population acquires the cancer incidence rate of the host country. For example, Japanese populations in western countries typically acquire the higher breast and colon cancer rates of the host country within a generation or two. Incidence of cancer may also be influenced by gender. For example, gastric cancer shows about a two-fold higher incidence in males than females in every region of the world studied ([Alberts et al., 2003](#)). While knowledge of the genetic basis of cancer helps us understand the molecular mechanism of carcinogenesis, knowledge of cancer-causing environmental factors is crucial to making important health and environmental policy decisions that may have far-reaching impact on human and animal health.

## AGENTS CAUSING CARCINOGENESIS

The three main classes of agents (carcinogens) causing cancers are chemicals, radiation and viruses. In this chapter, chemical carcinogenesis is emphasized, while viral and radiation carcinogenesis is also discussed briefly. Recent research also shows an important role of epigenetics in carcinogenesis.

**TABLE 26.1** Some known/suspected chemical carcinogens and their target organs

Chemicals/suspected carcinogens	Organs affected
Aflatoxin	Liver

## Chemical carcinogenesis

### Chemical carcinogens

Chemical carcinogens originate from both industrial and natural processes. In 1915, Yamagawa and Ichikawa pioneered the field of experimental cancer research when they produced tumors by repeated application of coal tars on the skin of rabbits. Many of the chemical carcinogens identified in early research were byproducts of industrial processes. Subsequent studies have revealed the carcinogenic potential of many other industrial, naturally occurring chemicals, as well as man-made chemicals. Chemical carcinogens may be synthetic (man-made) or of natural origin; they are extremely diverse in structure and belong to very different chemical classes, such as inorganic, organic, fibers, plastic, hormones, etc.

Based on their biological activities, chemical carcinogens can be classified as *genotoxic carcinogens* (DNA reactive) and *non-genotoxic carcinogens* (non-DNA reactive, epigenetic). Genotoxic carcinogens can be further classified as *direct carcinogens* (active without metabolic activation) and *indirect carcinogens* or *procarcinogens* (active after metabolic activation). Table 26.1 lists some of these chemical carcinogens and the organs affected by them.

### Biological process of chemical carcinogenesis

Experimental cancer research with carcinogenic chemicals led to the realization that chemical carcinogenesis is a multistep process. The pathogenesis of cancer involves many individual events, such as metabolic activation (biotransformation) of a procarcinogenic chemical to a DNA-reactive compound (in the case of indirect

genotoxic carcinogens), covalent binding to DNA, induction of heritable mutations and finally expression of the mutant phenotype at the molecular level (e.g., altered gene expression). All these changes result in altered cellular function, cellular transformation and neoplastic growth, and spreading of the transformed cells to other parts of the body. These events in the pathogenesis of cancer have been distilled into three distinct steps to describe the multistep nature of carcinogenesis; the steps are *initiation*, *promotion* and *progression* (Foulds, 1954). *Tumor initiation* involves introduction of heritable genetic change in a normal cell; *tumor promotion* involves clonal expansion of the initiated cell resulting in the formation of a benign tumor; and *tumor progression* involves the conversion of a benign tumor into a malignant one. Malignancy in cancers is characterized by anaplasia (reversion of cellular differentiation), invasiveness and metastasis.

In order for the tumors to develop, *the target tissue must be exposed to an initiator first and then repeatedly exposed to promoters*. If the time gap between the exposure to initiator and promoter varies from a week to a year, tumors will still develop. However, if the exposure to promoter is first and is followed by exposure to initiator, tumors will not develop. After the promotion event, the cancer cell acquires further heritable changes that lead to malignancy. Figure 26.1 shows the importance of the sequence of exposure to tumor initiator and tumor promoter in the development of cancer.

### Initiation

In the initiation phase, the chemical or its reactive metabolite causes a permanent change in the DNA of the target cell(s), such as a mutation, a distortion of the DNA structure with further consequences, elimination of a component of DNA (bases or sugars) or errors in DNA repair (Pitot, 2002). Thus, initiation is a genetic process. The chemical causing initiation is called an *initiator*. Once a target cell is initiated, initiation is irreversible. An initiated cell by itself is not a cancer cell because it has not acquired the property of uncontrolled growth. Additionally, all initiated cells do not produce tumors because many undergo programmed cell death or *apoptosis*. In order for an initiated cell to transform into a cancer cell and eventually produce a detectable tumor, promotion is necessary.

Some examples of tumor initiators are benz[a]pyrene; 7,12-dimethylbenz[a]anthracene; 3-methylcholanthrene; 2-acetylaminofluorene; dimethylnitrosamine; diethylnitrosamine, etc. The mechanism of tumor initiation by many initiators involves the formation of depurinating adducts, that is, the initiator forms an adduct with the purine bases, and removal of these purine adducts ultimately leads to a transition or transversion mutation in

**FIGURE 26.1** The target tissue must be exposed to an initiator first, followed by repeated exposure to promoters in order for the tumors to develop. If the time gap between the exposure to initiator and promoter varies from a week to a year, tumors will still develop. However, if the exposure to promoter is first and is followed by exposure to initiator, tumors will not develop. Also, if the exposure to promoter is not repeated and spaced over time, tumors are not likely to develop even if the exposure to promoter occurs after exposure to initiator.

the DNA. For example, 7,12-dimethylbenz[a]anthracene (DMBA) involves the formation of adducts in which DMBA is bound through its 12-methyl group to the N-7 position of adenine (major adduct) or guanine (minor adduct). Removal of the N-7 purine adducts leads to depurination and mutation, such as A→T transversion in *ras* oncogene. Some DNA lesions can be repaired. For example, exposure to the tumor initiator *N*-methyl-*N*-nitrosourea (MNU) results in the modification of guanine into *O*<sup>6</sup>-methylguanine in the DNA of the target tissue. Failure to repair the *O*<sup>6</sup>-methylguanine lesion leads to G→A transition. The "suicide enzyme" *O*<sup>6</sup>-methylguanine-DNA methyltransferase (MGMT) repairs this lesion. Transgenic mice overexpressing MGMT are less sensitive to tumor development in the tissue overexpressing the enzyme because of the increased repair of *O*<sup>6</sup>-methylguanine (Becker *et al.*, 1996, 2003; Liu *et al.*, 1999; Qin *et al.*, 2000). Experiments with

MGMT transgenic mice have also demonstrated that the *O*<sup>6</sup>-methylguanine lesion is possibly also involved in tumor progression (Qin *et al.*, 2000; Becker *et al.*, 2003).

Although a methyl group is the preferred substrate, MGMT can also repair DNA lesions by removing larger and complex alkyl groups, such as ethyl, propyl, butyl, benzyl and 2-chloroethyl groups, which makes MGMT an alkyltransferase rather than a methyltransferase. Repair of the *O*<sup>6</sup>-methylguanine by MGMT involves a cysteine residue in its active site (Cys145 in human MGMT). The methyl group becomes covalently attached to this cysteine residue, and this modification results in the inactivation of MGMT, which is then ubiquitinated and degraded by the proteasome. Hence MGMT's name – "suicide enzyme." Removal of other alkyl groups occurs through the same mechanism. Because MGMT is a suicide enzyme, continued DNA repair by MGMT requires *de novo* MGMT synthesis.

### Promotion

Tumor promoters alter the expression of genetic information of the cell, as well as, in many cases, inhibit programmed cell death (Pitot, 2002). Tumor promoters usually influence the proliferation of initiated cells, which results in the proliferation of preneoplastic cells and formation of benign focal lesions, such as enzyme-altered foci in the liver, nodules in the mammary gland, polyps in the colon and papillomas in the skin. Because tumor promoters alter the expression of genetic information without changing the DNA sequence, tumor promotion is an epigenetic process. In addition to causing cell proliferation, tumor promoters appear to block apoptosis, thus leading to accumulation of the initiated cells as dysfunctional, non-differentiated cells within a tissue. Some of the lesions that develop due to promotion regress, but others acquire additional mutations and progress to malignant neoplasm. Tumor promotion is a reversible process up to a certain stage if the promoter is withdrawn.

Tumor promoters tend to be organ specific. For example, TPA (12-*O*-tetradecanoylphorbol-13-acetate, a phorbol ester isolated from croton oil) is skin specific. Chlordane, DDT (dichlorodiphenyltrichloroethane), TCDD (2,3,7,8-tetrachlorodibenzo-*p*-dioxin), phenobarbital,  $\beta$ -naphthoflavone, peroxisome proliferators and polybrominated biphenyls are hepatic tumor promoters; mirex (an organochlorine) is a promoter in both skin and liver; saccharin is a bladder tumor promoter.

### Progression

Tumor progression involves autonomous growth and metastasis of the malignant neoplasm. At the cellular level, chromosomal breakage and deletion, duplication or translocation of chromosomal fragments are

**FIGURE 26.2** DNA bases showing the sites where alkylation, arylamination and aralkylation reactions can occur resulting in the formation of DNA adducts (according to Dipple, 1995). N3 alkylation of guanine, although reported in the literature and shown in the figure, is less common than N7 alkylation.

hallmarks of tumor progression phase. Additional mutations in the oncogenes and tumor suppressor genes also accumulate during this phase. This is why tumor initiators can also cause tumor progression (Qin *et al.*, 2000; Becker *et al.*, 2003). Karyotypic instability and accumulation of additional mutations may reflect an ongoing selection of cells suitable for neoplastic growth and metastasis (Okey *et al.*, 1998).

Some putative tumor progression agents (with no initiator activity) that cause transition from promotion to progression include benzene, benzoyl peroxide and 2,5,2'5'-tetrachlorobiphenyl (Okey *et al.*, 1998).

#### Mode of action of chemical carcinogens

Both direct and indirect carcinogens (procarcinogens) interact with DNA, forming DNA adducts. Indirect carcinogens (procarcinogens) acquire carcinogenic properties after metabolic activation, forming the *ultimate carcinogen*, which is the reactive metabolite that covalently modifies DNA. The biological activity of the carcinogens depends on a balance between their activation and detoxification in the target tissue.

The majority of these compounds interact with DNA through three different types of chemical reactions (Dipple, 1995; Okey *et al.*, 1998). The reactions involve the transfer of (1) an alkyl group, (2) an arylamine group or (3) an aralkyl group to DNA. An arylamine contains an amine-substituted aromatic ring, while an aralkyl

(arylalkyl) contains an alkyl-substituted aromatic ring. An example of a reactive arylamine group is arylnitrenium ion while an example of a reactive aralkyl group is benzyl radical.

The DNA-reactive groups are generated through specific reaction chemistries, such as oxidation at carbon-carbon double bonds yielding alkylating or aralkylating agents; oxidation or reduction at nitrogen producing arylaminating agents; conjugations of hydroxy compounds producing aralkylating or arylaminating agents; and conjugation between glutathione with dihaloalkanes producing alkylating agents. There are, however, some carcinogens that do not fit these categories, such as acylating agents,  $\alpha,\beta$ -unsaturated aldehydes, chloroethylene oxide, etc. (Dipple, 1995).

#### Alkylation and alkylating agents

Alkylating agents add an electrophilic alkyl group ( $R-CH_2^+$ ), a carbocation, to electron-rich (nucleophilic) sites in DNA. Carcinogens that transfer alkyl residues to DNA include nitrosamines, aliphatic epoxides, aflatoxins, lactones, nitrosoureas, mustards, haloalkanes, aryl triazenes and sultones (Dipple, 1995).

The sites of substitution in DNA bases by alkylating agents are many and are indicated in Figure 26.2. Alkylating agents are produced by enzymatic reactions (e.g., P450 mediated). An example is the cytochrome P450 2E1 (CYP2E1)-mediated metabolism of

FIGURE 26.3 Metabolic activation pathway for dimethylnitrosamine.

FIGURE 26.4 Metabolic activation pathway for aflatoxin B1.

dimethylnitrosamine (DMN) (Figure 26.3). CYP2E1-mediated hydroxylation of a methyl group in DMN results in the formation of an unstable intermediate hydroxymethyl-methyl nitrosamine, which undergoes spontaneous demethylation forming monomethylnitrosamine (MMN) and releasing one molecule of formaldehyde. The MMN undergoes tautomerization to form methyl diazohydroxide, which undergoes spontaneous decomposition to first form the methyl diazonium ion and then methyl carbonium ion (CH<sub>3</sub><sup>+</sup>). The methyl carbonium ion is the ultimate highly reactive alkylating agent that methylates nucleophilic sites on DNA and proteins. Larger *N*-nitroso compounds, such as tobacco smoke-derived NNK ((4-methylnitrosamino)-1-(3-pyridyl)-1-butanone), are activated by cytochrome P450 1A2 (CYP1A2). Aflatoxin B1 (AFB<sub>1</sub>) is also bioactivated by P450. In humans, cytochromes P450 1A2 (CYP1A2) and P450 3A4 (CYP3A4) appear to be the most important in the metabolic activation of AFB<sub>1</sub> (Van Vleet *et al.*, 2002). Hydroxylation of the unsaturated C<sub>8</sub>-C<sub>9</sub> bond in AFB<sub>1</sub> results in the formation of a reactive epoxide intermediate, the 8,9 epoxide (Figure 26.4).

The AFB<sub>1</sub>-exo-8,9-epoxide is the most relevant epoxide; it forms DNA adducts almost exclusively at the N-7 position of guanine. This results in a GC→TA transversion mutation at the third position of codon 249 of the *p53* gene, which is thought to be a major mechanism of aflatoxin-induced carcinogenesis (Smela *et al.*, 2001).

#### Arylamination and arylaminating agents

Aromatic amines (arylamines), amides, aminoazo dyes, heterocyclic amines, etc. all undergo metabolic activation forming highly reactive, electrophilic aryl nitrenium ions (Ar-NH<sup>+</sup>). The major sites of substitution in DNA by arylaminating agents appear to be the C-8 position and the amino group of the purine nucleotides (Dipple, 1995). Potential arylamination sites in DNA bases by arylaminating agents are indicated in Figure 26.2. A prototypical example is the metabolic activation of 2-naphthylamine. *N*-oxidation by CYP1A2 forms the corresponding *N*-hydroxyarylamine (e.g., *N*-hydroxynaphthylamine), which can undergo a number of conjugation reactions forming sulfate,

**FIGURE 26.5** Metabolic activation pathway for 2-naphthylamine.

acetate or glucuronide conjugates. These conjugates can be excreted in the urine. In the acidic pH of urine, the conjugate dissociates and the *N*-hydroxynaphthyl moiety is protonated to form the nitrenium ion (Figure 26.5). Formation of the nitrenium ion, which is the ultimate carcinogen, explains why 2-naphthylamine is carcinogenic in the urinary tract and urinary bladder. *N*-acetyltransferase (NAT), which catalyzes the transfer of acetyl groups from acetyl-CoA to arylamines forming acetyl esters, shows a great deal of polymorphism across species. Among humans, there are slow and fast acetylators. In hamsters, acetylation is fast while in dogs and rats, acetylation is slow. These species differences in *N*-acetyltransferase activity as well as intra-species polymorphism can greatly influence the toxicity outcome of the substances in question.

#### *Aralkylation and aralkylating agents*

Polycyclic aromatic hydrocarbons (PAHs) and related compounds are capable of transferring an aralkyl group to DNA. Carcinogens that transfer an aralkyl group to DNA include the polycyclic aromatic hydrocarbons, alkyl benzenes, pyrrolizidine alkaloids and nitroaromatics that are activated through the formation of dihydrodiol epoxide (Dipple, 1995). A classic example of this class is benzo[a]pyrene, which is converted by cytochrome P450 1A1 (CYP1A1) to benzo[a]pyrene 7,8 epoxide. This epoxide is readily converted by epoxide hydrolase to the 7,8 dihydrodiol of benzo[a]pyrene. Benzo[a]pyrene 7,8 dihydrodiol, in

turn, is converted by CYP1A1 to the 7,8 dihydrodiol-9,10 epoxide of benzo[a]pyrene. This 9,10 epoxide is part of the bay region, electrophilic and resistant to hydration by epoxide hydrolase; therefore it readily attacks DNA bases, covalently binds DNA and induces mutation, such as mutation in the 12th codon of *H-ras* oncogene (Figure 26.6). Potential aralkylation sites in DNA bases by aralkylating agents are indicated in Figure 26.2.

#### *Cellular defense against DNA damage – DNA repair and removal of DNA adducts*

DNA adducts (the chemical-induced, covalently modified DNA bases) can alter the DNA structure and, in turn, molecular processes, such as replication and transcription. If not repaired or repaired incorrectly, these modifications may ultimately lead to mutations and eventually cancer, particularly if the adduct is located in an oncogene or tumor suppressor gene. There are a number of mechanisms to repair DNA adducts: (1) direct repair, (2) base excision repair (BER), (3) nucleotide excision repair (NER) and (4) mismatch repair (MMR).

In *direct repair*, the bond between the nucleotide and the adduct is broken, restoring the original conformation. For example, *O*<sup>6</sup>-methylguanine (*O*<sup>6</sup>-MeG) is repaired by MGMT (methylguanine DNA methyltransferase) by direct demethylation of the methylguanine. If methylguanine is not repaired, it will pair with thymine instead of cytosine during replication. In the following replication cycle, this thymine will pair with adenine in the

FIGURE 26.6 Metabolic activation pathway for benzo[a]pyrene.

complementary strand. The net result is a G:C→A:T transition mutation in the DNA. Such G:C→A:T transition mutations are known to activate the *ras* oncogenes in nitrosourea-induced mouse lymphomas and rat mammary tumors, as well as in azoxymethane (AOM)-induced aberrant crypt foci (ACF) (Dumenco *et al.*, 1993; Zaidi *et al.*, 1995). In animals that have photolyase, thymine dimers are also repaired by the direct repair mechanism that involves breaking of the bond causing the lesion.

*Base excision repair (BER)* mechanism works mainly on non-bulky base modifications such as those produced by methylation (in positions where it does not interfere with H-bonding, such as 3- or 7-methyladenine or 8-hydroxyguanine). These types of methylation patterns are produced by MNU (*N*-methyl-*N*-nitrosourea). These inappropriate bases are recognized and removed by specific DNA glycosylases, which cleave the *N*-glycosidic bond between the base and the sugar. As a result, the base is removed and the sugar-phosphate backbone of the DNA remains intact. This creates a base gap in the DNA, also called an AP site (apurinic or apyrimidinic

site). The AP site is then recognized by AP endonuclease, which introduces a nick 5' to the AP site. A third enzyme, deoxyribophosphodiesterase (an excision endonuclease), then produces a second nick 3' to the AP site and removes the base-less sugar-phosphate backbone. The resultant one nucleotide gap is filled in by DNA polymerase, and DNA ligase seals the gap.

*Nucleotide excision repair (NER)* is a versatile mechanism that can eliminate a wide range of structurally unrelated lesions. Bulky base modifications such as benzo[a]pyrene-guanine adducts caused by smoking, cisplatin-guanine adducts and psoralen-thymine adducts resulting from chemotherapy, UV-induced multiple thymine dimers, etc. are all repaired by NER. In humans, thymine dimers are repaired by NER because humans do not have photolyase. The mechanism of NER involves generation of two nicks by an excision nuclease, one on each side of the lesion. As a result, a small portion of the affected DNA strand is removed. DNA polymerase then continues the repair synthesis and ligase seals the gap.

*Mismatch repair (MMR)* mechanism repairs bases that violate Watson-Crick base pairing rules. The classic

example is that of *E. coli*. The sequence 5'-GATC-3' in *E. coli* DNA is methylated at adenine, and the sequences 5'-CCAGG-3' and 5'-CCTGG-3' are methylated at cytosine. When DNA replicates, the daughter strand methylation is delayed. As a result, the newly synthesized daughter strand is always undermethylated compared to the parental strand. If there is a base misincorporation, the MMR machinery (MutS-MutH-MutL complex) identifies the misincorporated base by scanning the methylation status of both strands. The mismatched base is excised from the undermethylated daughter strand. The same principle applies to eukaryotic DNA mismatch repair. Three eukaryotic protein heterodimers composed of Msh (MutS homolog) subunits recognize DNA mismatches with different but overlapping specificities: Msh2·Msh3, Msh2·Msh6 and (only in plants) Msh2·Msh7. A second heterodimer, Mlh1 (MutL homolog1)·Pms2, couples mismatch recognition to excision of the error-containing nascent DNA. Deficiencies in Msh2 dramatically increase mutation rates (Hoffman *et al.*, 2004). For example, in HNPCC (hereditary nonpolyposis colorectal cancer) and other human cancers, mutations in MMR genes, such as MSH2, MSH6, MLH1 and PMS2 have been observed (Buermeier *et al.*, 1999). Consistent with this finding, mice transgenic for Msh2 are tolerant to the carcinogenic effects of methylating agents (deWind *et al.*, 1995).

Apart from the above-mentioned mechanisms, two other mechanisms of DNA repair are recombination repair and strand break repair. In *recombination repair*, when DNA polymerase encounters an unrepaired lesion on the parental (template) strand during replication, it stops synthesis at that point and resumes synthesis at the next priming site. This leaves a gap in the daughter strand. This gap is filled by recombination with the other parental strand. This donor parental strand is then repaired by polymerase and ligase. *Strand break repair* may involve single or double-strand breaks. *Single-strand breaks* do not disrupt the integrity of the DNA. The intact single strand is coated by PARP 1 (Poly(ADP-ribose) polymerase-1) protein near the lesion site of the other strand. The single-strand break is then repaired as in excision repair. *Double-stranded breaks* are dangerous because they damage the integrity of the DNA. Double-stranded breaks can be repaired in two ways; either by crossing over or by synthesis-dependent strand-annealing repair. Various proteins (such as Ku) bind to the broken ends of the DNA to protect it and initiate the repair.

## Viral carcinogenesis

### Tumor viruses, oncogenes and tumor suppressor genes

A number of cellular genes are now implicated in carcinogenesis. These genes are of two types; oncogenes

and tumor suppressor genes. Broadly speaking, activation of oncogenes and inactivation of tumor suppressor genes may have similar consequences in terms of carcinogenesis. Oncogenes are found in cancer-causing viruses, which are of two types; DNA viruses with DNA genomes and RNA viruses with RNA genomes. DNA viruses with oncogenic potential are from six distinct viral families: hepatitis B viruses, simian virus 40 (SV40) and polyomavirus, papillomaviruses, adenoviruses, herpesviruses and poxviruses. In contrast, members of only one family of RNA viruses, the retroviruses, are capable of inducing oncogenic potential (Cooper, 1995).

### Retroviral oncogenes and their evolution

The discovery of retroviral oncogenes significantly advanced our understanding about the function of genes responsible for the induction of abnormal cell proliferation. They replicate inside the cell through a DNA intermediate, called provirus, which is integrated into the chromosomal DNA of the infected cell. Transforming viruses (viruses capable of inducing malignant transformation of animal cells) do not need the oncogene for their replication. Viral oncogenes (*v-onc*) are derived from cellular proto-oncogenes (*c-onc*). Cellular proto-oncogenes contain introns while the corresponding viral oncogenes generally lack introns. Thus viral oncogenes originated in the host through recombination between the genome of a non-transforming retrovirus and a cellular oncogene. This was demonstrated in studies on the *v-src* oncogene by Hanafusa and colleagues in the early 1980s.

Figure 26.7 shows how a cellular proto-oncogene (*c-onc*) could be acquired by the viral genome. Transforming viruses preferentially integrate at the fragile sites on the host genome. These fragile sites correspond to the hot spots of recombination. Integration of the provirus in the genome next to the *c-onc* produces a transcription unit under the control of the viral LTR (long terminal repeats). Transcription of this unit produces a viral/cellular hybrid RNA. Intact viral RNAs are also produced from other integrated proviruses. These intact viral RNAs and hybrid RNAs, through reverse transcription and recombination, capture the processed cellular proto-oncogene as part of the viral genome. The captured processed cellular proto-oncogene now becomes a retroviral oncogene (*v-onc*).

### Activation of oncogenes

Retroviral oncogenes (*v-onc*) are altered versions of normal cellular genes called proto-oncogenes. The function of the *v-onc* product is similar or identical to that of the proto-oncogene (*c-onc*) product, but its expression is generally unregulated. Proto-oncogenes may be activated by mutation, chromosomal rearrangement or

**FIGURE 26.7** Mechanism by which a cellular proto-oncogene (*c-onc*) is captured by retrovirus to give rise to a viral oncogene (*v-onc*).

gene amplification. Chromosomal rearrangements, such as translocations and inversions, can activate proto-oncogenes by dysregulation of their transcription (e.g., transcriptional activation) or by gene fusion. For example, the product of the *ras* oncogene differs from that of the normal proto-oncogene by one base which is caused by a point mutation in the 12th codon (GGC→GTC) resulting in one amino acid change (Gly→Val). An example of oncogene activation through gene amplification is *myc*, which codes for a transcription factor that plays a role in cell division. One third of all neuroblastomas show *myc* oncogene amplification that inversely correlates with the prognosis. Such amplification of the *myc* oncogene results in the generation of a very high amount of its product. Generation of a high amount of *myc* oncogene product can also be due to high levels of transcription. This has been reported in Burkitt's lymphoma where translocation of the *myc* proto-oncogene from its normal location (chromosome 8) to chromosome 14 brings it close to the immunoglobulin heavy chain gene promoter. As a result, *c-myc* now finds itself in a region of vigorous transcriptional activity, with a consequent overproduction of its product. Another example of chromosomal translocation and dysregulation of proto-oncogene is found in chronic myelogenous leukemia (CML). In CML, a reciprocal translocation occurs between chromosomes 9 and 22 [t(9;22)]. A portion on the long arm of chromosome 9 (9q) containing the *abl* gene is

translocated next to the *bcr* (*breakpoint cluster region*) gene on the long arm of chromosome 22 (22q). The altered chromosome 22 is called the Philadelphia chromosome (Ph'). The *bcr-abl* produces higher levels of a fusion protein Bcr-Abl, which has constitutive protein tyrosine kinase activity in the Abl portion of the protein. The Bcr portion of this fusion protein can bind to various adaptor molecules. As a result, this fusion protein can associate with many proteins involved in the mitogenic signaling pathway, causing activation of mitogenic signaling and increased cell proliferation. Some other oncogenes associated with cancers of various organs are *hst* (stomach cancer), *met* (osteosarcoma), *bcl-1* (B cell leukemia), etc.

#### *Inactivation of tumor suppressor genes*

Tumor suppressor genes, which also participate in the regulation of normal cell growth, are usually inactivated by point mutations or truncation of their protein sequence coupled with the loss of the normal allele. The first mutation may be inherited or somatic. The second mutation will often be a gross event leading to loss of heterozygosity and tumor suppressor function. This mechanism provides support to the two-hit hypothesis in which he applied statistical analysis to compare patients with hereditary and nonhereditary forms of retinoblastoma. Knudson hypothesized that one germ

line copy of the damaged gene that is inherited in the hereditary form of retinoblastoma was not sufficient to trigger the development of this cancer. A second hit to or loss of the good copy in the gene pair was necessary to produce retinoblastoma. Frequent loss of heterozygosity in the tumor cells provides support to Knudson's hypothesis. Analysis of linkage markers in retinoblastoma cells and normal cells from the same individual shows that the markers that are heterozygous in normal cells are hemizygous in tumor cells, indicating the loss of the normal allele in the tumor cells (second hit).

#### *Functions of oncogene and tumor suppressor gene products*

Oncogene products are called oncoproteins. Proto-oncogenes encode proteins that are mostly involved in the regulation of cell growth, division and differentiation. Consequently, proto-oncogenes encode products that can act as growth factors, growth factor receptor-associated tyrosine kinases, membrane-associated non-receptor tyrosine kinases, G-protein-coupled receptors, membrane-associated G-proteins, serine-threonine kinases, transcription factors and regulators of programmed cell death.

Growth factors play important roles in cell cycle control, and they signal a cell to either enter the G1 phase or bypass it. The right amount of growth factors should be produced at the right time, or else cell cycle control may be dysregulated. Examples of oncogene-encoded growth factors are *sis* oncogene-encoded platelet-derived growth factor (PDGF) B chain and *int-2* oncogene-encoded fibroblast growth factor (FGF)-related growth factor. Receptor-associated and non-receptor tyrosine kinases as well as G-proteins, G-protein-coupled receptors and serine-threonine kinases all encode products that are important in regulating the transduction of mitogenic signals in the cell, thereby regulating normal cell division. In most cases, these oncogenes encode mutant forms of the proteins so that they are not subject to the on-off regulation in response to mitogenic signals. In other words, the mitogenic signal is perpetually "on," resulting in uncontrolled cell proliferation.

Oncogenes, such as *src* and *abl*, encode protein tyrosine kinases that are membrane-associated, while *erbB*, *neu* and *fms* encode transmembrane kinases. An example of an oncogene encoding a GTP-binding GTPase is *ras*. Normal GTP-binding proteins (G-proteins), including *ras*, are important signal transducers. The active form binds GTP and transduces the mitogenic signal, whereas hydrolysis of GTP to GDP inactivates the protein and terminates the signal. Further activation involves exchange of GDP for GTP. Mutant forms of *ras* exist in an inactive GDP-bound form, resulting in a perpetual "on" mode of the mitogenic signal. Oncogenes encoding transcription factors also act by the same principle. The proto-oncogene products of *fos* (Fos) and *jun* (Jun)

form a heterodimer to produce the transcription factor *activator protein-1* (AP-1). Mutant AP-1 may act in a constitutive manner and does not require activation by its inducers, such as phorbol esters. Other oncogenes, such as *myc* and *myb*, also code for transcription factors that, when mutated, can cause aberrant transcriptional dysregulation.

The cell growth and division suppressor effects are also lost in mutant *p53* which is a tumor suppressor gene and whose product (p53 protein) is a transcription factor. The three-dimensional structure of p53 protein with its target DNA molecule defined the core domain and the amino acids involved in DNA binding (Cho *et al.*, 1994). These amino acids that are involved in DNA binding show the highest mutation rate in various cancers. This demonstrates how mutations in tumor suppressor genes can abrogate their tumor suppressor function by disrupting the transcriptional regulation of their target genes. Another role of p53 is to regulate apoptosis or programmed cell death by up-regulating the pro-apoptotic gene *Bax*. Mutant p53 cannot mediate apoptosis; thus cells with unrepaired DNA damage are prevented from undergoing apoptosis. Survival of these cells and their subsequent division may lead to the development of cancer cells.

Mutagenic chemicals that can disrupt the structure and/or expression of these proto-oncogenes can cause their oncogenic activation. For example, phorbol ester is a known activator of AP-1-mediated transcription. The procarcinogen 1,2 dimethylhydrazine has been reported to induce mutation in *ras* which was detectable in preneoplastic and neoplastic rat colonic mucosa (Jacoby *et al.*, 1991).

## **Radiation carcinogenesis**

### *Radiation dose and risk*

In the following discussion, radiation will refer to only ionizing radiation. A radiation dose to tissue is expressed as *absorbed energy per unit tissue mass*. Gray (Gy) is the unit of radiation dose and is quantified as 1 joule/kg. The older unit *rad* is still used and 1 rad = 0.01 Gy. Carcinogenic potential depends upon the absorbed dose (energy).

LET (linear energy transfer; *L*) is a measure of the rate at which energy (*E*) is deposited to the absorbing medium per unit distance (*l*) traversed by the radiation ( $L = dE/dl$ ; if the distance traversed is measured in mm, then  $L = \text{keV/mm}$ ). Consequently, high LET radiations (e.g.,  $\alpha$ -particles, neutrons, heavy ions, pions, also known as pi mesons) will deposit greater amount of energy than low LET radiations (e.g.,  $\gamma$ -rays, X-rays, electrons) in the absorbing media. Human skin can stop

$\alpha$ -particles from penetrating and reaching the internal organs. This is because  $\alpha$ -particles deposit most of their energy onto the skin and may damage the skin in that process. Both alpha and beta particles penetrate cell membranes more easily than they penetrate human skin. Therefore, ingesting or inhaling radioactive chemicals that can emit  $\alpha$ - or  $\beta$ -particles can pose serious threats to human health.

In the case of tissue exposure, the energy deposited by the radiation causes ionizations and the generation of free radicals, which cause macromolecular damage. Thus, high-LET radiations are more destructive to biological materials than low-LET radiations because at the same dose, low-LET radiations induce the same number of radicals more sparsely within a cell, whereas high-LET radiations transfer most of their energy to a small region of the cell. The localized DNA damage caused by dense ionizations from high-LET radiations is more difficult to repair than the diffuse DNA damage caused by the sparse ionizations from low-LET radiations.

Experimental studies with animals as well as epidemiological studies indicate that higher or continual radiation exposure increases the incidence of specific cancers. Increased incidence of lung cancer has been observed among uranium miners, fluorspar miners, zinc and iron ore miners (Adams and Cox, 1997). Gottlieb and Husen (1982) studied the incidence of lung cancer among American Indians. According to the authors, lung cancer has been a rare disease among the Indians of the southwestern United States, but the advent of uranium mining in the area has been associated with an increased incidence of lung cancer among Navajo uranium miners. The study centered on Navajo men with lung cancer who were admitted to the hospital from February 1965 to May 1979. Of a total of 17 patients with lung cancer, 16 were uranium miners. The cause of the lung cancers is the  $\alpha$ -particle radiation from the inhaled radon gas emanating from the radium present in the ore. Another well-documented example of radiation-induced cancer is the occurrence of osteosarcoma among workers in luminous dial watch factories. Workers used to lick the paint brush to maintain sharp edges and, in the process, consumed radium-226 and radium-228. The ingested radium deposited in the bone and was the source of short range  $\alpha$ -particles. A recent example of radiation-induced increases in thyroid cancer comes from the Chernobyl incident. The nuclear reactor explosion at Chernobyl in 1986 resulted in substantial contamination of some parts of Belarus, Ukraine and Bryansk. Immediately after the accident, these regions were contaminated with cesium-137 as well as various isotopes of iodine, including iodine-131 (Stsjazhko *et al.*, 1995). Cesium-137 is a very dangerous radioisotope to the environment because of its long-term effects. Its half-life of about 30 years ensures that it stays in the environment for a very long time. The

authors reported that of those who continued to live in the contaminated region and consume locally produced milk for the 3 months after the accident, most (about 85%) of the radiation dose to the thyroid was derived from iodine-131, while the remainder was from short-lived isotopes of iodine. The incidence of thyroid cancer among children under 15 was 30.6 per million during 1991–1994 as compared to 0.3 during 1981–1985. Another source of human data on carcinogenesis by ionizing radiation is from the A-bomb survivors from Hiroshima and Nagasaki. Data show that in the first 5–10 years after the exposure, the risk of leukemia increased rapidly but declined thereafter. The risk of solid tumors in many organs also increased significantly (Okey *et al.*, 1998).

### *Mechanism of radiation-induced carcinogenesis*

An absorbed dose of 1 Gy generates about  $2 \times 10^5$  ionizations within the mammalian cell. Approximately 1% of these ionizations occur in the DNA itself (Adams and Cox, 1997). Consequent DNA damage involves both single-strand and double-strand breaks, most of which are repaired within a few hours. Single-strand breaks, which are more frequently caused by low-LET radiations, are more readily repaired than double-strand breaks. UV radiation is known to distort the DNA strands by causing thymine dimers. In animals that have photolyase, thymine dimers are repaired by the direct repair mechanism that involves breaking of the bond causing the lesion. Humans do not have photolyase, so thymine dimers in humans are corrected by the nucleotide excision repair (NER) mechanism.

Ionizing radiation and oxidative stress are closely associated. Irradiated cells produce damaging reactive oxygen species (ROS), which can cause severe damage to cellular macromolecules including nuclear DNA (Spitz *et al.*, 2004; Wu *et al.*, 1999). A cell's oxidative status plays an important role not only at the time of radiation exposure, but also long after exposure. Irradiation may produce ROS for several minutes or even hours after exposure (Spitz *et al.*, 2004).

At the cytological level, an extension of radiation-induced DNA damage is chromosome breakage. Radiation can induce aberrant intra-chromosomal crossing over that involves one or both chromatids. Radiation can also induce non-disjunction of homologous chromosomes resulting in trisomy in the  $F_1$  offsprings, as well as other chromosomal aberrations, such as translocations and deletions (Adams and Cox, 1997). Chromosomal breaks have been shown to occur at a higher frequency in certain fragile sites. In other words, depending on the energy, radiation can cause increased genomic instability.

Unrepaired DNA strand/chromosomal breaks can lead to deletion or scrambling of gene sequences. The hypoxanthine–guanine phosphoribosyltransferase (HPRT) locus

on X-chromosome is known to undergo such aberrations following high radiation exposure (Thacker, 1986). If the target gene is an oncogene or a tumor suppressor gene, then radiation-induced mutations in oncogenes or inactivation of tumor suppressor genes may have serious consequences.

It should be emphasized that most of the molecular data on radiation-induced carcinogenesis have been obtained from laboratory studies, including *in vitro* studies. For humans, epidemiological studies from accidents and disasters involving ionizing radiation also demonstrate increased risk of cancer owing to high exposure to radiation. Nevertheless, little reliable information is currently available on the increased risk factors for high-LET radiations or about dose-rate effects of low-LET radiations (Okey *et al.*, 1998).

## EPIGENETIC BASIS OF CARCINOGENESIS

The mechanisms of carcinogenesis discussed above mostly involve changes in DNA sequence and/or integrity. However, carcinogenesis has an important epigenetic component as well. Epigenetics can be defined as heritable changes in gene expression that are not accompanied by changes in DNA sequence. Three main mechanisms of epigenetic regulation of gene expression are mediated by: (1) DNA methylation, (2) histone modifications and (3) small non-coding RNA, such as microRNA (miRNA).

Aberrant gene function and altered patterns of gene expression are key features of cancer. Growing evidence shows that acquired epigenetic abnormalities participate with genetic alterations to cause this dysregulation (Jones and Baylin, 2007). Proper coordination of temporal silencing and activation of gene expression is the key to the orchestration of normal life processes. Dysregulation of gene expression results in dysregulation of normal physiological processes, which, in turn, paves the way to the development of diseased states. Epigenetic changes can collaborate with genetic changes to cause the evolution of a cancer because they are mitotically heritable (Jones and Baylin, 2007).

The epigenetic basis of carcinogenesis is probably the most widely studied epigenetic basis of diseased state. Studies over the last 30 years or so have confirmed that the genome in a cancer cell/tissue is characterized by global (genome-wide) hypomethylation and site-specific promoter hypermethylation. Many of these epigenetic changes probably occur very early in cancer development and may contribute to cancer initiation (Jones and Baylin, 2007; Sharma *et al.*, 2010).

Global DNA hypomethylation basically has two effects: increasing genomic instability and activating growth promoting genes. Hypomethylation affects repeat sequences, leading to increased genomic instability by promoting chromosomal rearrangements. Additionally, hypomethylation of retrotransposons can result in their activation and translocation to other genomic regions, thus increasing genomic instability. DNA hypomethylation can also activate growth-promoting genes (proto-oncogenes), thereby inappropriately turning on mitogenic signals. DNA hypomethylation can also lead to the loss of imprinting (LOI). In contrast to hypomethylation, which increases genomic instability and activates proto-oncogenes, site-specific hypermethylation contributes to tumorigenesis by silencing tumor suppressor genes (Sharma *et al.*, 2010). Interestingly, methylation-mediated silencing of tumor suppressor genes provides one of the two hits advocated in Knudson's two-hit theory (Knudson, 1971).

Silencing of gene expression in carcinogenesis also involves global loss of transcription-activating histone modifications, such as acetylation and activating methylation. All known histone acetylations are transcription activating. In contrast, certain histone methylations are transcription activating, such as histone H4 lysine 20 methylation, whereas others are transcription repressing, such as histone H3 lysine 9 and lysine 27 methylation. Loss of histone acetylation is carried out by histone deacetylase (HDAC), which is often overexpressed in various types of cancer (Sharma *et al.*, 2010). In addition to the loss of transcription-activating modifications, cancer cells also have active transcriptional silencing modifications, such as histone H3 lysine 9 and lysine 27 methylation.

The third arm of epigenetic regulation, the miRNAs, also shows widespread dysregulation of expression in carcinogenesis. Because miRNAs are involved in transcriptional regulation, cell proliferation and apoptosis, dysregulation in their expression can promote tumorigenesis. Oncogenic miRNAs (oncomirs) target tumor suppressors and growth inhibitory pathways, and are often up-regulated in various types of cancer. Examples of oncomirs are miR-21 (targets the tumor suppressor "phosphatase and tensin homolog deleted on chromosome 10 (PTEN)," which is up-regulated in human glioblastoma; miR-155, which is up-regulated in breast, lung and several hematopoietic malignancies; miR-17-92 cluster, which targets pro-apoptotic gene *Bim*, is overexpressed in many different types of cancer. In contrast to oncomirs, tumor suppressor miRNAs target oncogenes and growth promoting pathways, and are often down-regulated in cancers. For example, miR-15 and miR-16 target the anti-apoptotic gene *BCL2* and are down-regulated in chronic lymphocytic leukemia; miR-127 targets *BCL6* and is down-regulated in prostate and bladder tumors (Sharma *et al.*, 2010).

Therefore, the normal cellular epigenetic landscape is significantly altered in cancer. The underlying mechanisms that initiate these global changes are yet to be fully understood, so are the causative versus correlative changes. Nevertheless, recent studies indicate that some changes occur very early in cancer development and may contribute to cancer initiation (Jones and Baylin, 2007; Sharma *et al.*, 2010).

## CLASSIFICATION OF CARCINOGENS

The most widely used systems for classifying carcinogens comes from the International Agency for Research on Cancer (IARC). The U.S. Environmental Protection Agency (EPA) has also developed a very similar classification scheme. In the past 30 years, IARC has evaluated about 900 likely candidates for their cancer-causing potential in humans. Most of the agents are of probable, possible or unknown risk. Only about 90 are classified as carcinogenic to humans. The IARC classification scheme is described below.

Known human carcinogen

**Group 1** – There is sufficient evidence of carcinogenicity in humans.

Probable human carcinogen

**Group 2A** – There is limited evidence of carcinogenicity in humans, but sufficient evidence of carcinogenicity in experimental animals, and strong evidence that carcinogenesis in experimental animals is mediated by a mechanism that also operates in humans.

Possible human carcinogen

**Group 2B** – There is limited evidence of carcinogenicity in humans, and less than sufficient evidence of carcinogenicity in experimental animals.

Not classifiable for human carcinogenicity

**Group 3** – The evidence of carcinogenicity is inadequate or limited in experimental animals.

Not likely to be a human carcinogen

**Group 4** – Not carcinogenic to humans.

## ASSAYS FOR CARCINOGENS

Tests most frequently used to determine carcinogenic activity include (1) long-term bioassays and (2) short-term assays. Recently, building of databases of known/suspected carcinogenic compounds has helped in the development of computer programs that can predict the carcinogenic potential of new compounds using quantitative structure–activity relationships (QSAR). These

programs provide additional tools when there is ambiguous data or insufficient data to infer safety. Some of the common tests under each category are discussed below.

### Long-term bioassays

The National Toxicology Program (NTP) rodent cancer bioassay evolved out of the National Cancer Institute (NCI) cancer bioassay protocol of the 1970s. Groups of 50 or more rodents are assigned to control or treatment groups. Test substances are given by intubation, dietary or drinking water consumption, or dermal or inhalation exposure. The route of delivery is determined based on the most likely route that humans are expected to be exposed through. Dosing starts at age 5–6 weeks and lasts for 2 years, at which point surviving animals receive a complete histopathologic examination (Bucher, 2002). In a classic lifetime tumor bioassay, the maximum tolerated dose (MTD) for a particular chemical is determined in a dose-range finding study; then doses close to the MTD are administered to male and female rats and mice for 2 years. A statistically significant, chemical-associated increase in tumor count is taken as evidence of carcinogenicity (Parsons and McKinzie, 2001). These assays are expensive and time consuming. Additionally, the use of MTD is debatable since the high doses of chemical used to develop tumors often lead to cytotoxic effects in animal tissues. This cytotoxicity may lead to cell proliferation and other promoter-like events. Nevertheless, the rodent tumor bioassay has been used for carcinogenicity testing for many years, primarily for four reasons. First, the rodent tumor bioassay fulfills an obvious need for an experimental system. Second, *in vivo* exposure and tumor development are considered more relevant endpoints for assessing human cancer risk than *in vitro* tests with bacterial or mammalian cells or non-tumor endpoints. Third, the rodent tumor bioassay has been used for many years without disastrous human health consequences, and, finally, at the present time there is no other “ideal” assay with which to replace the rodent tumor bioassay (Parsons and McKinzie, 2001).

### Short-term assays

These assays may be used to determine a chemical’s ability to cause *mutational events*, *chromosomal aberrations* or *DNA damage in vitro* or *in vivo*.

Two major assays used to detect *mutational events* are the *Ames test* for bacterial mutagenesis and the *mammalian cell gene mutation assays*. The Ames test was developed in the early 1970s by Bruce Ames at the University of California, Berkeley. The Ames method is based on inducing growth in genetically altered strains of *Salmonella typhimurium*. These strains need histidine

in order to grow. If the chemical agent under investigation is a mutagen, it should cause some of the bacteria to undergo mutations so that some of these bacteria (revertants) can grow without histidine, just like the wild-type bacteria (hence, reverse mutation test). To evaluate the effect of metabolism on the chemical, such tests are performed in the presence and absence of S9 fraction (post-mitochondrial supernatant fraction). The S9 fraction contains liver enzymes, generally from a rat treated with a broad-spectrum xenobiotic-metabolizing enzyme inducer, such as Arochlor 1254. There are several altered *Salmonella* strains used in the Ames test, such as TA97, TA98, TA100, TA1535 and TA1537; each varies in sensitivity to specific mutagens. The Ames test yields a number, such as the number of revertants (could be as high as several hundred thousands) per microgram of a pure chemical (mutagen).

Unlike the Ames test, which measures reverse mutation (from mutant back to wild type), the mammalian cell gene mutation assays measure forward mutations at a specific locus. Two of the well-studied loci are the thymidine kinase (TK) locus in mouse lymphoma cells and the hypoxanthine–guanine phosphoribosyl transferase (HPRT) locus in Chinese hamster ovary cells. To evaluate the effect of metabolism of the chemical, such tests are performed in the presence and absence of S9 fraction.

Cytogenetic analysis for *chromosomal aberrations* enables direct observation of various chromosomal aberrations. Cells are arrested in metaphase, examined microscopically and the chromosomal aberrations are enumerated. The cells used could be Chinese hamster ovary (CHO) cells, human peripheral blood lymphocytes or rat lymphocytes. An alternate cytogenetic approach is the observation and scoring of *micronuclei*. A micronucleus is formed during the metaphase/anaphase transition. It may arise from a lagging chromosome (*aneugenic* event resulting in chromosome loss) or an acentric chromosome fragment detaching from a chromosome after breakage (*clastogenic* event). Another assay for measuring chromosomal aberrations is the *sister chromatid exchange* (SCE) assay, which detects the ability of a chemical to enhance the exchange of DNA between two sister chromatids of a duplicating chromosome. Sister chromatid exchange means a reciprocal interchange of the two chromatid arms within a single chromosome. This exchange is visualized during metaphase. Detection of SCEs requires some means of differentially labeling sister chromatids, such as by the incorporation of bromodeoxyuridine (BrdU) into chromosomal DNA for two cell cycles. The most commonly used assays employ mammalian bone marrow cells or peripheral blood lymphocytes, often from rodent species. All these assays could be performed in the presence and absence of metabolic activation systems (S9).

Detection of *DNA damage* can also be determined using the *comet assay*. The comet assay is also known as

the *single cell gel electrophoresis assay* and it is a very useful and sensitive technique for detecting DNA damage at the level of a single cell. The technique acquired its name from the comet-like shape of the DNA of the cells which can be seen under the microscope after the procedure. This technique was developed by Swedish researchers Östling and Johansson in 1984, and was later modified by Singh and coworkers in 1988 as the alkaline comet assay. The alkaline comet assay is much more sensitive than the original comet assay. In the comet assay, cells of interest are suspended in low-melting agarose and layered onto slides pre-coated with agarose. Cells are lysed under high salt concentration to release the damaged DNA. The DNA is subjected to unwinding under neutral/alkaline conditions to allow DNA supercoils to relax. Electrophoresis of this DNA under neutral or highly alkaline (pH > 13) conditions allows the broken ends to migrate forming the “comets.” After neutralization, staining is done using fluorescent DNA dyes (e.g., ethidium bromide, propidium iodide, Hoescht 33258, acridine orange, etc.) and the DNA is visualized under a fluorescent microscope. The slides are then scored by counting; 50–100 cells are counted per sample, either by manual counting or using specific software. Both qualitative and quantitative assessment of DNA damage is carried out. The alkaline comet assay enables the detection of single-strand DNA breaks in individual cells. Therefore, the alkaline comet assay can measure low levels of DNA strand breaks.

The ability of a genotoxic agent to induce DNA lesions can also be investigated by measuring the *unscheduled DNA synthesis* (UDS). The assay measures DNA repair synthesis after excision and removal of a stretch of DNA containing the lesion induced by chemical and physical agents. The assay is based on the incorporation of tritium-labeled thymidine into the DNA of mammalian cells that are not in the S phase (DNA synthesis phase) of the cell cycle. The uptake of tritium-labeled thymidine can be determined by autoradiography or by liquid scintillation counting of DNA from the treated cells.

### Structure–activity relationships and carcinogenicity

Over 70,000 chemicals are used commercially and more than 100,000 naturally occurring chemicals have been identified (Cramer *et al.*, 1978). It would be virtually impossible, impractical, economically unfeasible and not sensible to test all these compounds for potential carcinogenicity. This then begs the question – how do scientists (toxicologists, food technologists, drug developers, regulatory scientists, etc.) make decisions as to the safety of chemicals for addition to food, as drugs, for industrial use and/or for prioritizing those that do require additional, extensive toxicity testing?

**FIGURE 26.8** Hypothetical chemical structure highlighting (in black) the Ashby and Tennant structural alerts for carcinogenicity (Ashby and Tennant, 1989). (a) Alkyl ester of either phosphonic or sulphonic acids, (b) aromatic nitro groups, (c) aromatic azo groups, by virtue of their reduction to an aromatic amine, (d) aromatic ring *N*-oxides, (e) aromatic mono- and di-alkylamino groups, (f) alkyl hydrazines, (g) alkyl aldehydes, (h) *N*-methylol derivatives, (i) monohaloalkenes, (j) a large family of *N* and *S* mustards ( $\beta$ -haloethyl), (k) *N*-chloramines (substructure has not been associated with carcinogenicity, but potent genotoxic activity has been reported), (l) propiolactones and propiosultones, (m) aromatic and aliphatic aziridiny derivatives, (n) both aromatic and aliphatic substituted primary alkyl halides, (o) derivatives of urethane (carbamates), (p) alkyl *N*-nitrosamines, (q) aromatic amines, their *N*-hydroxy derivatives and the derived esters, (r) aliphatic epoxides and aromatic oxides, (s)  $\alpha,\beta$ -unsaturated carbonyls, (t) halogenated methanes ( $X = \text{H, Cl, Br, I}$  in any combination).

One of the ways toxicologists have prioritized the study of chemicals is through the use of structure–activity relationship analysis (SAR). Structure–activity relationships can be divided into two classes: (1) qualitative relationships and (2) quantitative relationships.

#### Qualitative structure–activity relationships

A qualitative structure–activity relationship is an association between a molecular (sub)structure and the presence or absence of a biological activity, or the capacity to modulate a biological activity imparted by another substructure. A substructure associated with the presence of a biological activity is sometimes called a structural alert. Therefore, chemicals with similar chemical structures and physicochemical properties should exhibit similar

biological activity whether it is a specific toxic effect or a pharmacological activity.

Qualitative SAR analyses rely upon a finite knowledge base of compounds that have been previously tested and the researcher's ability to identify key structural similarities between the compound of interest and compounds in the previously established knowledge bases. A variety of classification schemes, such as those detailed in Cramer *et al.* (1978), Cheeseman *et al.* (1999) and FDA's Red-book (Rulis *et al.*, 1984), have been developed that exploit these relationships, most of which are based on classifying either mutagens or carcinogens into broad categories. The Ashby and Tennant classification scheme (Ashby and Tennant, 1989) for structural alerts (Figure 26.8) is probably one of the simplest approaches to identifying potential carcinogenic activity of a compound

**TABLE 26.2** A list of Ashby and Tennant structural alerts and functional-group list compiled by Munro (Me = —CH<sub>3</sub>, E = —CH<sub>2</sub>CH<sub>3</sub>)

**Aryl and heterocyclic ring substituted amino- and nitro- derivatives (Ashby AA class)**

Bioactivation to nitrenium ions (Ar—N<sup>+</sup>—H) by N-hydroxylation to arylhydroxylamines (Ar—N(OH)R)  
 1°- and 2°-amines [Ar—NHR, where R may be —H, —Me, —Et or activated Me or Et] (examples mostly 1°-amines and include hydrochloride salts)  
 3°-amines [Ar—NR<sup>1</sup>R<sup>2</sup>, where R<sup>1</sup> and R<sup>2</sup> = —Me, —Et] [few examples mostly di-Me]  
 2°-acetamides and -formamides [Ar—NHCOR, where R = —H, —Me or activated Me] (examples mostly R=NHCOMe)  
 nitroarenes [Ar—NO<sub>2</sub>] (reduction to nitroarene; many examples)  
 nitrosoarenes [Ar—N=O] (reduction to arylhydroxylamine)  
 arylhydroxylamines [Ar—N(OH)R]

**Nitroso compounds (Ashby NO class)**

Bioactivation to carbonium (R<sub>2</sub>CH<sup>+</sup>) or diazonium ions (RN<sup>+</sup>≡N) by oxygenation at α-C to diazohydroxides (R-N=N—OH). Substrate must possess —H, —OH on α-C or α-C=O relative to nitrogen.  
 N-nitroso-N-dialkylamines [R<sup>1</sup>R<sup>2</sup>N—N=O, most examples are from this class]  
 N-nitroso-N-alkylamides [R<sup>1</sup>R<sup>2</sup>N—N=O, where R<sup>2</sup> = COR<sup>3</sup>, R<sup>3</sup> = alkyl or aryl]  
 N-nitroso-N-alkylureas [R<sup>1</sup>R<sup>2</sup>N—N=O, where R<sup>2</sup> = CONR<sup>3</sup>R<sup>4</sup>, R<sup>3</sup> = H, R<sup>4</sup> = alkyl or aryl]  
 N-nitroso-N-alkylcarbamates (aka -urethanes) [R<sup>1</sup>R<sup>2</sup>N—N=O, where R<sup>2</sup> = CO<sub>2</sub>R<sup>3</sup>, R<sup>3</sup> = alkyl or aryl]  
 N-nitroso-N-alkylnitriles [R<sup>1</sup>R<sup>2</sup>N—N=O, R<sup>2</sup> = CN]  
 N-nitroso-N-hydroxylamines [R-N(OH)NO]

**Hydrazo derivatives (Ashby NZN class)**

Bioactivation to carbonium (R<sub>2</sub>CH<sup>+</sup>) or diazonium ions (RN<sup>+</sup>≡N) by oxygenation at α-C. R groups may be alkyl or aryl, but one must possess —H, —OH on α-C or α-C=O relative to nitrogen  
 hydrazines [R<sup>1</sup>R<sup>2</sup>N—NR<sup>3</sup>R<sup>4</sup>] (oxidation to azo then azoxy derivative; examples mostly terminal R<sub>2</sub>N—NH<sub>2</sub>)  
 azoxy alkane [R<sup>1</sup>-N<sup>+</sup>(O<sup>-</sup>)=N-R<sup>2</sup>, R is C<sub>4</sub> or less]

**Natural electrophiles (Ashby ALK class)**

Aliphatic halides [R-CH<sub>2</sub>X, where R is ≤ C<sub>4</sub> and contains activating groups; not more than one—X per C]  
 Benzylic halides [Ar—CH<sub>2</sub>X, where X = Cl, Br, I]  
 Oxiranes and aziridines [3-membered O- and N-containing rings]  
 Propiolactones [4-membered ring containing—CO<sub>2</sub>-]  
 Alkyl esters of sulfonic [RSO<sub>2</sub>OR<sup>1</sup>] and sulfuric [ROSO<sub>2</sub>OR<sup>1</sup>] acids (where R<sup>1</sup> = Me or Et)  
 Alkyl esters of phosphonic [RP(=O)(OR<sup>1</sup>)<sub>2</sub>] and phosphoric [(RO)<sub>2</sub>P(=O)OR<sup>1</sup>] acids (where R<sup>1</sup> = Me or Et)  
 Mixed alkyl esters of phosphoric acid [(RO)<sub>2</sub>P(=S)OR<sup>1</sup>, where R<sup>1</sup> = Me or Et]  
 Haloethylamines [—NCH<sub>2</sub>CH<sub>2</sub>X]  
 Haloalkylethers [ethyl (—OCH<sub>2</sub>CH<sub>2</sub>X) and methyl (—OCH<sub>2</sub>X)]  
 α-Halocarbonyl [R(C=O)CH<sub>2</sub>X] or α-halohydroxy [R(CHOH)CH<sub>2</sub>X]  
 Haloamines [R<sub>2</sub>N—X]  
 α,β-Unsaturated carbonyls [R<sub>2</sub>C=C—C(=O)R, where R is an aldehyde, ketone, ester, amide group]  
 Allylic halides and alkoxides [R<sub>2</sub>C=C—CH<sub>2</sub>X, where X = Cl, Br, I or OR]

**Other alerting groups (Ashby SA+ class)**

Halogenated methanes [CH<sub>m</sub>X<sub>n</sub>, where m + n = 4]  
 Vinyl halides [R<sup>1</sup>R<sup>2</sup>C=CHX, where X = Cl, Br or I]  
 Polycyclic aromatic hydrocarbons  
 Isocyanate [R-N=C=O]  
 Isothiocyanate [R-N=C=S]  
 Azoarenes [R<sup>1</sup>-N=N—R<sup>2</sup>, R<sup>1</sup> and R<sup>2</sup> are aryl] (-SO<sub>3</sub>H group on both rings non-alerting)

Source: Bailey *et al.* (2005)

that has unknown toxicity. This classification scheme correlates a structural alert (a fragment of a chemical's structure that may participate in an electrophilic attack on DNA) with a compound's carcinogenic potential. These alerts can be used in the evaluation of a chemical to give a qualitative sense of the compound's likelihood of being carcinogenic. A list of structural alerts proposed by Ashby and Tennant (Ashby and Tennant, 1989) and functional groups cited by Munro (Munro *et al.*, 1996) are summarized in Table 26.2.

In addition to using classification schemes to identify compounds for potential concerns, there are a number of structurally searchable databases that allow one to identify close structural analogs of the compound in question. Publicly available examples are the National Library of Medicine's (NLM) ChemIDPlus (NLM, 2005) and EPA's Distributed Structure-Searchable Toxicity (DSSTox) Public Database Network (EPA, 2005). Several commercial databases of toxicity information are also available; two examples are Leadscope Enterprise and Lhasa Limited's Vitic

Nexus. The data from these analogs may be used to extrapolate a numerical risk value for a potential toxic effect.

### Quantitative structure–activity relationships

Quantitative SAR analysis (QSAR) is a quantitative relationship between a biological activity (e.g., toxicity) and one or more descriptors that are used to predict the activity. In other words, QSAR utilizes the existing scientific data to make decisions about the potential carcinogenicity of new and/or untested chemicals using predictive models based on some type of algorithm (e.g., relating structural topology, chemical bond types, bioavailability, solubility, etc. to some toxic endpoint – genotoxicity, carcinogenicity, etc.) powered by computer software.

There are several commercially available predictive toxicity programs currently available. These programs can be divided into two general categories: (1) human expert/rule-based programs such as OncoLogic and Derek Nexus and (2) human expert/statistical/correlative programs such as Leadscape Model Applier, TOPKAT and MCASE-MC4PC. Detailed information on these and other QSAR software packages is readily obtained on the World Wide Web.

An example of a human expert/rule-based program is OncoLogic, which predicts carcinogenicity based on the chemical structure of a substance (Woo *et al.*, 1995). Analysis is done by applying a decision tree approach that incorporates the knowledge of mechanisms of action and human epidemiological studies. OncoLogic contains four carcinogenicity modules focused on non-dietary fibers, metals or organometallics, polymers and organics. The output consists of a justification of the potential carcinogenicity, or lack thereof, using a tiered level of concern (low, marginal, low-moderate, moderate, high moderate or high) with identification of the chemicals used in the decision tree analysis that led to the conclusions.

An example of a statistical/correlative program is MCASE-MC4PC (MultiCase, 2005), which has several predictive modules, including mutagenicity, carcinogenicity and teratogenicity. MultiCase uses an algorithm to identify all possible 2–10 atom fragments for each discrete chemical structure within a diverse training set of substances. The program then identifies fragments (structural alerts or biophores) that are primarily associated with the biological activity (e.g., carcinogenicity) of the training set and modulators of the activity, such as bioavailability and conformational comparisons. New substances with unknown toxicity are screened by entering the structure of the untested substance using a structural drawing program. The molecule in question is reduced to all possible 2–10 atom fragments and these fragments are compared to the list of structural alerts (biophores) and modulators identified within the training set. The output consists of scalar units, referred to as

CASE units, in increasing activity values ranging from 10 to 80. A case rating of 10–19 is considered non-toxic, 20–29 are marginal (equivocal, weak or inconsistent findings), 30–49 are moderately potent toxins (*trans*-gender, single site tumors) and 50–80 are potent toxins (*trans*-species, *trans*-gender, multiple site tumors in rodents). The biophores identified by the program are subjected to a set of human expert rules that take into account specificity, positive predictivity, false positives and coverage to arrive at a decision as to whether the test molecule is carcinogenic, the level of confidence with the prediction and whether the program-generated CASE-unit score is appropriate.

In the past, (Q)SAR models were typically used individually. However, more recently there has been a movement to use multiple (Q)SAR models in conjunction with each other to make toxicity predictions. The use of multiple (Q)SAR models, both statistical and rule-based predictive software, can be used to decrease false-positive and false-negative predictions. However, this approach presents a unique problem; how do you deal with the multiple predictions from these packages? You can take the approach of one positive prediction among the set means the compound is positive for the tested endpoint. This is a very conservative approach that could lead to additional, unnecessary testing. Alternatively, you could use a consensus approach (Matthews *et al.*, 2008) where the compound is only called positive or negative if all of the models result in the same prediction. This approach may reduce the concerns expressed regarding the false-positive and false-negative rates of the models since the models are all in agreement. However, a significant challenge still remains; what do you do with a compound where the QSAR models' predictions are conflicting? An approach to these conflicting predictions is that they are evaluated to ensure that they are valid and are weighed against predictions from rule-based systems such as Derek Nexus, Oncologic and, when possible, information gathered from commercial and/or publicly available toxicity databases, thus creating a set of "checks and balances" by using multiple models that evaluate the chemicals in different ways, such as: biophores, whole molecule properties, fingerprints, as well as rule-based predictions. Using these predictions in conjunction with toxicity data on the compound, or its structural analogs, a weight-of-evidence approach can be used to predict the potential toxicity or provide sufficient evidence to support additional data/testing needs. This approach of using multiple (Q)SAR models has the added benefit that if the chemical in question is not covered by one (Q)SAR model, it will most likely be covered by one or more of the other models.

Predictive software continues to be refined and its concordance, specificity and predictivity are approaching

the 90+ percent range. As long-term testing becomes increasingly expensive and controversial (animal rights activism, etc.), look for these QSAR software packages to play an increasing and more prominent role in the safety assessment of new chemical substances.

The accumulated knowledge of the metabolism, chemical reactivity, exposure, structure–activity relationships and other relevant information on chemicals, when scientifically and systematically woven together, can allow us to make expert judgments as to the potential risks due to exposure to chemicals in food, air and water. These judgments can be used to identify those compounds that merit further toxicity testing and those not worth pursuing. All schemes used to make these decisions must be thoroughly tested, be transparent and evoke confidence in the results both in the public and the scientific communities.

## CONCLUSIONS

After more than three decades since President Nixon declared the “War on Cancer” with the enactment of the National Cancer Act, the war still continues. Routine check-up has been effective in the early diagnosis and cure of certain forms of cancer, such as colon cancer and breast cancer. Inventions in modern medicine have further added to better prognosis. Nevertheless, cancer largely remains an incurable disease unless it is detected early.

In spite of significant advances in our knowledge on the molecular mechanisms of carcinogenesis, scientists seem to have a long way to go before all these advances in knowledge could be translated into effective and curative therapy. In the meantime, more work is needed to understand certain aspects of carcinogenesis, such as the mechanisms of action of non-genotoxic carcinogens. However, the accumulated knowledge on various aspects of carcinogenesis has definitely helped scientists make appropriate risk assessment and health policy recommendations. Finally, recent progress in the science of genomics has provided scientists with renewed hope that further breakthroughs in cancer detection and therapy are not far away, allowing us to effectively control the disease.

# Oxidative stress and chemical toxicity

Manashi Bagchi, Shirley Zafra-Stone, Debasis Bagchi and Sangeeta Patel

## INTRODUCTION

Oxidative stress is characterized by the presence of an excess of oxidants caused by an imbalance between the formation and neutralization of reactive oxygen species (ROS) (Behl, 1999). Oxidative stress can lead to the formation of chain reaction byproducts, which create a potentially unstable cellular environment by causing massive cellular injury and extensive damage to the lipids, proteins and biological macromolecules. Oxidative stress has also been linked to tissue damage, advancing age associated dysfunctions and a broad spectrum of degenerative diseases including atherosclerosis, arthritis, cardiovascular dysfunctions, diabetes, metabolic syndrome and chronic fatigue syndrome (Javadov *et al.*, 2011; Maicas *et al.*, 2011).

Free radicals or oxidants are highly reactive, unstable molecules that have an unpaired electron in their outermost electron orbit which reacts with or oxidizes various cellular components and biological macromolecules including proteins, DNA, RNA, lipids, fatty acids and advanced glycation end products, i.e., carbonyls (Stohs and Bagchi, 1995). These reactions between cellular components and free radicals lead to DNA single- and double-strand breaks, DNA fragmentation, lipid peroxidation, protein oxidation products, mitochondrial malfunction, cell membrane damage, lactate dehydrogenase (LDH) leakage and eventually programmed cell death (apoptosis) and unprogrammed cell death (necrosis). Examples of free radicals or oxidizing molecules are hydrogen peroxide ( $\text{H}_2\text{O}_2$ ), singlet oxygen, superoxide anion ( $\bullet\text{O}_2^-$ ), hydroxyl radical ( $\bullet\text{OH}$ ), peroxy radical ( $\text{ROO}\bullet$ ), reactive nitrogen oxides and peroxynitrite ( $\text{ONOO}^-$ ) (Table 27.1).

The steady-state formation of free radicals is normally balanced by a similar rate of consumption of antioxidants. Various pathologic processes disrupt this balance by increasing the formation of free radicals in proportion to the available antioxidants and antioxidant enzymes. Enhanced formation of free radicals induces a compromised effect on the body's immune system leading to inflammation, ischemia-reperfusion injury of different organs, apoptosis, necrosis and altered gene expression. Enhanced formation of free radicals and oxidative stress, and inadequate antioxidant activity are associated with a broad spectrum of disease states such as cardiovascular dysfunctions, chronic fatigue syndrome, hepatitis, cancer, autoimmune disorders, HIV and AIDS, cancer and diverse neurodegenerative diseases (Stohs, 1995; Stohs and Bagchi, 1995). This chapter describes chemical-induced oxidative stress and its consequences on animal health.

## OXIDATIVE STRESSORS: HEAVY METALS AND ENVIRONMENTAL TOXICANTS

Numerous evidence suggests that exposure to structurally diverse environmental toxicants, including heavy metals, polyhalogenated or polycyclic aromatic hydrocarbons, pesticides and their carcinogenic counterparts, and mycotoxins may involve a common cascade of events which includes the production of ROS and oxidative stress leading to lipid peroxidation (Bagchi *et al.* 1998a, 2002; Hussein and Brasel, 2001), DNA single-strand breaks and fragmentation (Stohs *et al.*, 1997),

TABLE 27.1 Structurally diverse oxygen free radicals involved in oxidative stress and chemical toxicity

Oxidant	Description
$\bullet\text{O}_2^-$ , superoxide anion	One-electron reduction state of $\text{O}_2$ , formed in many autooxidation reactions and by the electron transport chain. Rather unreactive but can release $\text{Fe}^{2+}$ from iron-sulfur proteins and ferritin. Undergoes dismutation to form $\text{H}_2\text{O}_2$ spontaneously or by enzymatic catalysis and is a precursor for metal-catalyzed $\bullet\text{OH}$ formation.
$\text{H}_2\text{O}_2$ , hydrogen peroxide	Two-electron reduction state, formed by dismutation of $\bullet\text{O}_2^-$ or by direct reduction of $\text{O}_2$ . Lipid soluble and thus able to diffuse across membranes.
$\bullet\text{OH}$ , hydroxyl radical	Three-electron reduction state, formed by Fenton reaction and decomposition of peroxynitrite. Extremely reactive, will attack most cellular components
$\text{ROOH}$ , organic hydroperoxide	Formed by radical reactions with cellular components such as lipids and nucleobases.
$\text{RO}\bullet$ , alkoxy and $\text{ROO}\bullet$ , peroxy radicals	Oxygen-centered organic radicals. Lipid forms participate in lipid peroxidation reactions. Produced in the presence of oxygen by radical addition to double bonds or hydrogen abstraction.
$\text{HOCl}$ , hypochlorous acid	Formed from $\text{H}_2\text{O}_2$ by myeloperoxidase. Lipid soluble and highly reactive. Will readily oxidize protein constituents, including thiol groups, amino groups and methionine.
$\text{ONOO}^-$ , peroxynitrite	Formed in a rapid reaction between $\bullet\text{O}_2^-$ and $\text{NO}\bullet$ . Lipid soluble and similar in reactivity to hypochlorous acid. Protonation forms peroxynitrous acid, which can undergo homolytic cleavage to form hydroxyl radical and nitrogen dioxide.

membrane damage with decreased membrane fluidity (Bagchi *et al.*, 1992), apoptosis (Stohs, 1995), glutathione depletion (Bagchi *et al.*, 1996a), altered calcium homeostasis (Bagchi *et al.*, 1997, 1998a, 1998b), enhanced release of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), induction of stress/heat shock protein 90 (Von Burg and Lui, 1993), stimulation of oncogene expression, and inhibition of tumor suppressor genes (Schwarz *et al.*, 1995).

## Chromium, lead, cadmium and other heavy metals

### Chromium

Chromium exists predominantly in two valence states: Cr(III) and Cr(VI). Cr(III) is an essential micronutrient, while Cr(VI) is carcinogenic. Cr(VI) is a highly reactive transition metal widely known to cause allergic dermatitis as well as toxic and carcinogenic effects (Von Burg and Lui, 1993; Goyer 1996). Chromate,  $(\text{CrO}_4)^{2-}$ , is the most dominant form of Cr(VI) in neutral aqueous solutions and can readily cross cellular membranes via non-specific anion carriers (Danielsson *et al.*, 1982). The ability of Cr(VI) to induce an oxidative stress is well known. Von Burg and Lui (1993) and Barceloux (1999) summarized the acute and chronic toxicity, neurotoxicity, dermatotoxicity, genotoxicity, carcinogenicity, immunotoxicity and general environmental toxicity of chromium. Chromium (VI)-induced internucleosomal DNA fragmentation, inhibition of macromolecular synthesis and apoptosis have been demonstrated in cultured Chinese hamster ovary cells, and low-dose exposure to chromium has been shown to potentiate cell proliferation and apoptosis (Von Burg and Lui, 1993; Manning *et al.*, 1994; Barceloux 1999). Vitamin E,

glutathione and oxygen scavengers can decrease chromate-induced cytotoxicity, lipid peroxidation and DNA damage, with vitamin E exhibiting the greatest protective effect (Sugiyama, 1991). Both forms of chromium undergo redox cycling (Stohs and Bagchi, 1995). Various investigators have examined the mechanism of DNA cleavage by Cr(VI). The results indicate that Cr(VI) complexes are produced in the reduction of Cr(VI) by cellular reductants such as NADPH that react with hydrogen peroxide to generate hydroxyl radicals (Shi and Dalal, 1989). The hydroxyl radicals are believed to be the initiators of the primary events in Cr(VI) cytotoxicity and are responsible for causing DNA strand breaks. The reactions involved in the redox cycling of Cr(III) and Cr(VI) are:

Although Cr(III) is much less nontoxic compared with Cr(VI), Cr(III) can be reduced to Cr(II) by biological reductants such as NADH and L-cysteine (Ozawa *et al.*, 1993). The newly formed Cr(II) reacts with hydrogen peroxide to produce hydroxyl radical, which is presumably responsible for tissue-damaging effects including the production of DNA damage. In summary, both Cr(VI) and Cr(III) are biologically active oxidation states of chromium, although Cr(VI) is much more toxic and produces greater oxidative stress and carcinogenesis. Both oxidation states of chromium are involved in redox cycling with the production of ROS.

Investigations have shown that sodium dichromate (Cr(VI)) more effectively induces the formation of ROS and

causes oxidative tissue and DNA damage compared with Cr(III) (Manning *et al.*, 1994; Bagchi *et al.*, 1995a). The effect of an oral low dose (0.05 LD<sub>50</sub>) of Cr(VI) (2.5 mg/kg/d) on brain mitochondrial and microsomal lipid peroxidation, excretion of urinary lipid metabolites, and brain nuclear DNA single-strand breaks in Sprague-Dawley rats has shown that maximum increases in these parameters occur between 60 and 75 days of treatment. The results of these experiments clearly indicate that low-dose subchronic administration of Cr(VI) induces oxidative stress, resulting in tissue damaging effects that may contribute to the toxicity and carcinogenicity of Cr(VI) (Bagchi *et al.*, 2002).

The *p53* tumor suppressor gene plays a major role in the regulation of cellular stress response including oxidative stress, in part through the transcriptional activation of genes involved in cell cycle control, DNA repair and apoptosis (Amundson *et al.*, 1998). Many factors have been shown to contribute to control the activation of *p53*, and the downstream response to *p53* activation may vary depending on the cellular environment or other modifying factors in the cell, including exposure to diverse xenobiotics. Because *p53* is activated in response to DNA damage and different signaling mechanisms, the role of the *p53* gene was assessed to unveil the mechanism of structurally diverse xenobiotics-induced oxidative stress and toxicity in the brain tissues (Bagchi *et al.*, 2000). Measured biomarkers included superoxide anion production (cytochrome *c* reduction), DNA

fragmentation and lipid peroxidation (TBARS). The levels of these parameters were not significantly different in the brains of untreated C57BL/6NTac and C57BL/6TSG *p53*-deficient mice. A comparative study was conducted using different types of environmental stressors including TCDD, endrin, naphthalene and Cr(VI) in *p53*-deficient mice. Treatment of C57BL/6NTac mice with a 0.01 LD<sub>50</sub> dose of TCDD, endrin, naphthalene and Cr(VI) increased cytochrome *c* reduction by 1.5- to 1.6-fold in brain tissues as compared to the control animals, although under the same conditions, approximately 1.7- to 2.4-fold increases in cytochrome *c* reduction were observed in brain tissues of *p53*-deficient mice (Table 27.2). Similar results were obtained in brain lipid peroxidation (Table 27.3) and DNA fragmentation (Table 27.4) (Bagchi *et al.*, 2000).

Approximately 2.5-, 3.0-, 3.4- and 2.5-fold increases in cytochrome *c* reduction were observed in brain tissues of C57BL/6NTac mice after treatment with 0.10 LD<sub>50</sub> doses of TCDD, endrin, naphthalene and Cr(VI) compared to corresponding values in untreated control animals. Under the same conditions, approximately 4.0-, 6.9-, 5.1- and 3.7-fold increases in cytochrome *c* reduction were observed in brain tissues of TSG-*p53* mice compared to control animals. In comparison, at a 0.10 LD<sub>50</sub> dose, TCDD, endrin, naphthalene and Cr(VI) induced 1.6-, 2.3-, 1.5- and 1.5-fold greater increases in cytochrome *c* reduction in brain tissues of *p53*-deficient mice than in

TABLE 27.2 Cytochrome *c* reduction in brain tissue (nmoles reduced/15 min/mg of protein)

Treatment	0.50 LD <sub>50</sub>		0.10 LD <sub>50</sub>		0.01 LD <sub>50</sub>	
	C57BL/6NTac	<i>p53</i> -deficient	C57BL/6NTac	<i>p53</i> -deficient	C57BL/6NTac	<i>p53</i> -deficient

DNA fragmentation was determined in brain tissues of C57BL/6NTac and p53-deficient mice 24 h after treatment with a 0, 0.01, 0.10 or 0.50 LD<sub>50</sub> dose of the four xenobiotics. Each value is the mean ± SD of four experiments.<sup>a-c</sup> Values within a column with non-identical superscripts are significantly different ( $p < 0.05$ ) from each other.

C57BL/6NTac animals (Table 27.2). Similar results were obtained in brain lipid peroxidation and DNA fragmentation (Tables 27.3 and 27.4) (Bagchi *et al.*, 2000).

Treatment of C57BL/6NTac mice with 0.50 LD<sub>50</sub> dose of TCDD, endrin, naphthalene and Cr(VI) increased cytochrome *c* reduction by 5.7-, 5.4-, 5.3- and 4.1-fold in brain tissues compared to corresponding values in untreated control animals, although under the same conditions, approximately 8.1-, 10.1-, 9.6- and 7.7-fold increases in cytochrome *c* reduction were observed in brain tissues of p53-deficient mice. In comparison, at a 0.50 LD<sub>50</sub> dose, TCDD, endrin, naphthalene and Cr(VI) induced 1.4-, 1.9-, 1.8- and 1.9-fold higher increases in cytochrome *c* reduction in brain tissue of p53-deficient animals than in C57BL/6NTac mice (Table 27.1) (Bagchi *et al.*, 2000). These results demonstrate the massive production of ROS and oxidative DNA damage by Cr(VI) and other xenobiotics. Similar results were obtained in brain lipid peroxidation and DNA fragmentation (Tables 27.3 and 27.4).

### Lead

Lead is another major environmental toxicant that causes neurological, hematological and gastrointestinal dysfunction. Prolonged exposure to lead may also cause reproductive impairment, hypertension and nephropathy. Furthermore, lead slows nerve conduction, alters calcium homeostasis, inhibits enzymes and stimulates synthesis of binding proteins (Goyer, 1996; Stohs and Bagchi, 1995). Although lead is not considered a transition metal, the catalysis of peroxidative reactions by lead may be a major contributor to the toxic effects of this metal. Various studies have shown that administration of lead to experimental animals results in the production of lipid peroxidation in the brain tissues. Administration of vitamin E prevents enhanced lipid peroxidation and toxicity of lead (Ramstoeck *et al.*, 1980), providing additional evidence for the role of oxidative stress in lead toxicity. As observed with cadmium and nickel, lead produces a compensatory increase in tissue glutathione levels. Results involving the role of ROS and oxidative stress in the toxicity of lead are consistent with the results for other heavy metals (Stohs and Bagchi, 1995).

### Iron, copper, manganese and zinc

The brain, particularly the gray matter, is rich in metal ions such as iron (Fe), copper (Cu), manganese (Mn) and zinc (Zn), which may consist of significant concentrations within the range 0.1–0.5 mM (Hamai *et al.*, 2001). Experimental data have shown these metal ions are key factors in both the generation and defense against ROS and degenerative diseases. In neurological diseases, an abnormal reaction occurs between a protein and a redox-active metal ion promoting the formation of ROS, which can be detrimental to the nervous system and other organs (Jenner, 1996). ROS and oxidative stress significantly contribute to the pathophysiology of a broad spectrum of degenerative diseases (Cheng and Trombetta, 2004). Other studies have shown that rabbits fed a high-cholesterol diet in the presence of copper ions developed amyloid brain lesions and cognitive deficiencies (Bush *et al.*, 2003; Sparks and Schreurs, 2003).

### Oxidative stress by organophosphate and carbamate pesticides

Residential and industrial use of organophosphate and carbamate pesticides is widespread in the United States. According to the 1997 findings of the U.S. Environmental Protection Agency, over 40 organophosphate pesticides and 22 carbamate pesticides are the among 900 pesticides registered for use in the United States which pose the highest risks to animal health (Bagchi *et al.*, 2006). Organophosphates have been used extensively to control wide range of (sucking and chewing) pests of field crops, fruits and vegetables. The widespread use of the well-known organophosphate pesticide chlorpyrifos has raised major concerns about its potential to cause fetal or neonatal neurobehavioral damage, even at doses that do not evoke acute toxicity. Chlorpyrifos has been shown to inhibit replication of brain cells, to elicit alterations in neurotrophic signaling, governing cell differentiation and apoptosis, as well as to evoke oxidative stress (Bagchi *et al.*, 2006).

Recent studies indicate that toxic manifestations induced by these pesticides are associated with the

enhanced production of ROS which provides an explanation for the multiple types of toxic responses as well as a characteristic wasting syndrome. Most of these pesticides may also serve as common mediators in the activation of protein kinase C, oncogene expression, apoptosis and tumor formation. The ability to produce ROS *in vivo* with successive tissue damage was examined by brain lipid peroxidation and DNA single-strand breaks (DNA-SSB). Chemiluminescence, lactate dehydrogenase (LDH) leakage and DNA-SSB were assessed to determine the *in vitro* production of ROS. Organophosphates have also shown the mechanism involved in the induction of oxidative tissue damaging effects, including lipid peroxidation and nuclear DNA-SSB in *in vivo* models.

A comparative *in vitro* and *in vivo* effect of organophosphates such as chlorpyrifos and fenthion were assessed in cultured neuroactive PC-12 cells and in treated animals (Bagchi *et al.*, 1995a, b). Dissimilar polyhalogenated cyclic hydrocarbons, such as endrin and chlordane, and chlorinated acetamide herbicides, such as alachlor, were also compared to these organophosphates insecticides.

The ability to produce ROS *in vivo* with successive tissue damage was examined by hepatic and brain lipid peroxidation and DNA single-strand breaks (SSB). Chemiluminescence, lactate dehydrogenase (LDH) leakage and DNA-SSB were assessed to determine the *in vitro* production of ROS. These results clearly demonstrated that administration of organophosphates result in the *in vitro* and *in vivo* induction of brain lipid peroxidation, chemiluminescence response, LDH leakage and DNA-SSB, suggesting that the ROS and/or free radicals may be involved in the toxic manifestations of organophosphates and other structurally dissimilar pesticides. Furthermore, results indicate the tissue specificity of organophosphates with respect to the responses.

### *In vitro and in vivo generation of ROS and lipid peroxidation in the brain tissue by structurally dissimilar pesticides*

Organophosphate- and other xenobiotics-induced *in vivo* production of ROS and membrane damage in the brain tissue were assessed by brain lipid peroxidation and DNA damage. Endrin, chlordane, alachlor, chlorpyrifos and fenthion were administered orally to female Sprague-Dawley rats in two 0.25 LD<sub>50</sub> doses at 0 and 21 h and killed at 24 h. Lipid peroxidation assays were determined on the brain whole homogenates from control and treated animals according to the method of Buege and Aust (1972), based on the formation of thiobarbituric acid reactive substances (TBARS). Following treatment of the rats with chlorpyrifos, fenthion, endrin, chlordane and alachlor approximately 4.6- to 5.3-fold increases in brain lipid peroxidation were observed in brain homogenates. Similar results were obtained in cultured PC-12 cells using these pesticides. The effects of these pesticides on lipid peroxidation and DNA damage in brain homogenates are summarized in Table 27.5 (Bagchi *et al.* 1995a, b).

The effect of dichlorvos exposure on the lipid peroxidation and antioxidant defense system in different regions of the rat brain was investigated. An inhibition of acetylcholinesterase activity was used as an index of dichlorvos neurotoxicity. Dichlorvos exposure resulted in a significant decrease in glutathione peroxidase activity. The decreased levels of both reduced and oxidized glutathione as observed following dichlorvos exposure affected the GSH/GSSG ratio. The results also supported that the enzymes SOD and catalase may enhance the disposal of potentially toxic free radicals. Furthermore, the decrease in GSH levels may be a mechanism for the detoxification of dichlorvos in the brain and other organs (Julka *et al.*, 1992).

TABLE 27.5 Effects of pesticides on nuclear DNA-single strand breaks (DNA-SSB) in brain tissue and cultured PC-12 cells and lipid peroxidation (TBARS content) in Sprague-Dawley rats

Treatment	DNA-SSB (elution constant $\times 10^{-3}$ )		TBARS (nmol/mg protein)
	Brain tissue	Cultured PC-12 cells	
Control	7.9 $\pm$ 2.1 <sup>a</sup>	3.4 $\pm$ 0.4 <sup>a</sup>	5.4 $\pm$ 0.6 <sup>a</sup>
Endrin	15.0 $\pm$ 2.3 <sup>b</sup>	8.5 $\pm$ 0.9 <sup>b</sup>	12.7 $\pm$ 0.9 <sup>b</sup>
Chlordane	13.0 $\pm$ 1.0 <sup>b,c</sup>	7.6 $\pm$ 0.7 <sup>b</sup>	11.4 $\pm$ 1.1 <sup>b</sup>
Alachlor	17.0 $\pm$ 1.7 <sup>b</sup>	7.2 $\pm$ 0.6 <sup>b</sup>	19.6 $\pm$ 1.3 <sup>c</sup>
Fenthion	11.0 $\pm$ 0.8 <sup>c</sup>	8.6 $\pm$ 0.3 <sup>b</sup>	28.6 $\pm$ 2.0 <sup>d</sup>
Chlorpyrifos	11.0 $\pm$ 1.6 <sup>c</sup>	8.3 $\pm$ 0.5 <sup>b</sup>	25.0 $\pm$ 2.1 <sup>d</sup>

Female Sprague-Dawley rats received two 0.25 LD<sub>50</sub> doses of the pesticides in corn oil at 0 and 21 h and killed at 24 h. Control animals received the vehicle. Effects of 100 nM concentrations of the pesticides on DNA-single strand breaks (DNA-SSB) of cultured PC-12 cells at 24 h post-treatment were determined. DNA-SSB were determined by the alkaline elution method and are expressed as DNA elution constants. Lipid peroxidation was determined as the content of TBARS, using MDA as the standard. Each value is the mean  $\pm$  SD of at least 4–6 animals in each group. Values with non-identical superscripts are significantly different ( $p < 0.05$ ).

**FIGURE 27.1** Chemiluminescence production by brain homogenates *in vitro* following exposure to structurally diverse pesticides.

#### *Chemiluminescence response by chlorpyrifos, fenthion and other structurally diverse pesticides for generation of ROS*

The chemiluminescence assay is a non-specific test for the identification of ROS. The sustained chemiluminescence produced by brain tissues following treatment with chlorpyrifos, fenthion and other pesticides including alachlor, chlordane and endrin is presumably due to the continued production of ROS. The chemiluminescence responses produced following *in vitro* administration of these pesticides in brain tissues are shown in Figure 27.1. The chemiluminescence response produced by brain homogenates from pesticide(s)-treated rats rapidly increases, reaching a maximum between 6 and 8 minutes of incubation, while brain homogenates from control animals reach a peak chemiluminescence at 6 minutes. The chemiluminescence persisted for over 10 minutes. Increases of 2.9- and 2.4-fold were observed in the chemiluminescence responses in the brain homogenates of the animals treated with chlorpyrifos and fenthion. The greatest chemiluminescence responses in brain tissues were induced by chlorpyrifos (Bagchi *et al.*, 1995b, 2002).

#### *Lactate dehydrogenase leakage by chlorpyrifos, fenthion and other pesticides*

Organophosphates produce toxicological effects due to their ability to accumulate in the adipose tissue. Organophosphates exhibit similar abilities as inducers of hepatic drug metabolizing enzymes (Viviani *et al.*, 1978) and act as potent competitive and stereospecific inhibitors of ligand binding to specific types of brain receptors (Botham, 1990).

As an index of membrane and cellular damage, the release of lactate dehydrogenase (LDH) from cultured

PC-12 cells was measured as a function of concentration of the pesticides. Increased release of LDH into the media of cultured cells is indicative of cellular and membrane damage. Cultured PC-12 cells were incubated in the presence of 0, 50, 100 or 200 nM of chlorpyrifos, fenthion and other pesticides, and the release of LDH by the cells was measured after 24 h of incubation as an index of cytotoxicity. The amount of LDH released by these pesticides was concentration dependent. However, the differences in the release of LDH into the media were not significantly different at concentrations of 100 and 200 nM. Maximal release of LDH from cultured PC-12 cells was observed at 100 nM concentrations of the pesticides. Increases of 2.3-, 2.5-, 2.8-, 3.1- and 3.4-fold were observed in LDH leakage following incubation of the PC-12 cells with endrin, chlordane, alachlor, chlorpyrifos and fenthion, respectively (Table 27.6) (Bagchi *et al.*, 1995b, 2002).

An SDS polyacrylamide gel electrophoresis study demonstrated the overexpression of 60 and 90 kDa protein in hepatic, brain and lung tissues following treatment with structurally dissimilar pesticides (Figure 27.2). Enhanced expression of 90 kDa protein was also observed in cultured PC-12 cells following treatment with these pesticides (Figure 27.2) (Bagchi *et al.*, 1996b, 2002). Table 27.7 depicts the radioactivity ( $^{32}\text{P}$  counts/min) associated with Hsp89 $\alpha$  and Hsp89 $\beta$  mRNA expression in control and pesticide-treated cultured PC-12 cells. The cultured PC-12 cells were incubated with 50, 100 or 200 nM concentrations of the pesticides and the concentration-dependent effects of the pesticides were determined. At various concentrations of alachlor, endrin, chlorpyrifos and fenthion, the expression of Hsp89 $\alpha$  and Hsp89 $\beta$  significantly increased as compared to the control values.

TABLE 27.6 Concentration-dependent effects of pesticides on the release of LDH from cultured PC-12 cells

Treatment	Concentration of LDH in the media (U LDH/l)		
	50nM	100nM	200nM
Control	77.4 ± 9.2 <sup>a</sup>	76.9 ± 10.3 <sup>a</sup>	79.2 ± 8.6 <sup>a</sup>
Endrin	123.8 ± 16.5 <sup>b,c</sup>	178.1 ± 11.6 <sup>b</sup>	183.6 ± 20.2 <sup>b</sup>
Chlordane	100.6 ± 9.8 <sup>b</sup>	193.5 ± 20.4 <sup>b,c</sup>	212.4 ± 19.5 <sup>b,c</sup>
Alachlor	131.7 ± 11.4 <sup>c</sup>	216.7 ± 19.3 <sup>c</sup>	230.3 ± 22.6 <sup>c</sup>
Chlorpyrifos	147.1 ± 15.3 <sup>c,d</sup>	239.9 ± 20.8 <sup>c,d</sup>	241.0 ± 25.7 <sup>c,d</sup>
Fenthion	162.5 ± 13.7 <sup>d</sup>	263.2 ± 24.6 <sup>d</sup>	266.5 ± 20.4 <sup>d</sup>

PC-12 cells (25 × 10<sup>4</sup> cells/35mm Petri dish) in 2ml of RPMI 1640 were incubated for at least 3h to allow cell adherence and 50nM, 100nM, or 200nM concentrations of pesticides were added to the cultures in two equally divided portions at 0 and 24h. The incubation was continued at 37°C in an atmosphere of 5% CO<sub>2</sub> for 24h. Media were collected from the cultures and assayed for LDH activity. Data are expressed as the mean value of six experiments ± SD. Values with non-identical superscripts are significantly different (P < 0.05).

Genotoxicity of organophosphate

The detection of genotoxicity caused by organophosphate pesticides has also been determined using the single cell gel electrophoresis assay or comet assay. Chlorpyrifos and acephate were tested for their ability to induce *in vivo* genotoxic effect in leukocytes of Swiss albino mice (Rahman *et al.*, 2002). The mice were treated orally with doses ranging from 0.28 to 8.96mg/kg body weight of chlorpyrifos, or 12.25 to 392.00mg/kg body weight of acephate. A comet assay was performed on whole blood at 24, 48, 72 and 96h. A significant increase in mean comet tail length indicating DNA damage was observed at 24h post-treatment (P < 0.05) with both pesticides in comparison to cyclophosphamide (positive control) demonstrating the DNA damage was dose related. The mean comet tail length revealed a clear dose-dependent increase.

FIGURE 27.2 SDS polyacrylamide gel electrophoresis of the hepatic (a), brain (b) and lung (c) tissues from control and pesticide-treated rats, and cell lysates (d) from control and pesticide-treated cultured PC-12 cells. Lanes as follows: 1, control sample; 2, alachlor-treated sample; 3, endrin-treated sample; 4, chlordane-treated sample; 5, chlorpyrifos-treated sample; and 6, fenthion-treated sample.

TABLE 27.7 Radioactivity ( $^{32}\text{P}$  counts/min) associated with Hsp89 $\alpha$  and Hsp89 $\beta$  mRNA expression in control and pesticide-treated, cultured PC-12 cells

Treatment	Hsp89 $\alpha$			Hsp89 $\beta$		
	50nM	100nM	200nM	50nM	100nM	200nM
Control (DMSO)	637 $\pm$ 52 <sup>a</sup>	716 $\pm$ 73 <sup>a</sup>	754 $\pm$ 66 <sup>a</sup>	596 $\pm$ 34 <sup>a</sup>	634 $\pm$ 39 <sup>a</sup>	787 $\pm$ 55 <sup>a</sup>
Alachlor	2427 $\pm$ 211 <sup>b</sup>	3219 $\pm$ 255 <sup>b</sup>	3957 $\pm$ 265 <sup>b</sup>	2392 $\pm$ 181 <sup>b</sup>	3611 $\pm$ 263 <sup>b</sup>	4456 $\pm$ 328 <sup>b</sup>
Endrin	2042 $\pm$ 187 <sup>c</sup>	3315 $\pm$ 308 <sup>b</sup>	2821 $\pm$ 257 <sup>c</sup>	1808 $\pm$ 178 <sup>b</sup>	3544 $\pm$ 295 <sup>b</sup>	4030 $\pm$ 413 <sup>b</sup>
Chlordane	787 $\pm$ 64 <sup>d</sup>	893 $\pm$ 62 <sup>c</sup>	987 $\pm$ 71 <sup>d</sup>	682 $\pm$ 71 <sup>c</sup>	756 $\pm$ 84 <sup>c</sup>	941 $\pm$ 90 <sup>c</sup>
Chlorpyrifos	2287 $\pm$ 218 <sup>b,c</sup>	3626 $\pm$ 275 <sup>b</sup>	4573 $\pm$ 422 <sup>b</sup>	2938 $\pm$ 232 <sup>b,d</sup>	3885 $\pm$ 367 <sup>b,d</sup>	4744 $\pm$ 411 <sup>b</sup>
Fenthion	2642 $\pm$ 223 <sup>b</sup>	3711 $\pm$ 307 <sup>b</sup>	4388 $\pm$ 414 <sup>b</sup>	3182 $\pm$ 274 <sup>d</sup>	4312 $\pm$ 323 <sup>d</sup>	4418 $\pm$ 409 <sup>b</sup>

Cultured PC-12 ( $1 \times 10^7$ ) cells were incubated individually with either 50nM, 100nM or 200nM of alachlor, chlordane, chlorpyrifos or fenthion, and total RNA was isolated after 24h using the guanidiumisothiocyanate method. The RNAs were run on 1% agarose gels, transferred to nylon membranes and Northern blot analyses were performed by using  $^{32}\text{P}$ -labeled HSP89 $\alpha$  and HSP89 $\beta$  probes. Values are expressed as mean counts/min  $\pm$  SD of 4–6 animals. Values within each column with non-identical superscripts are significantly different ( $p < 0.05$ ).

A gradual decrease in mean tail length was noted from 48h post-treatment. By 96h of post-treatment the mean comet tail length reached control levels indicating repair of the damaged DNA.

Organophosphate-induced oxidative stress at the tubular level has been hypothesized as playing a role in the pathogenesis of acute tubular necrosis. Bidrin<sup>®</sup>, an organophosphate insecticide formulation with dicrotophos as the active ingredient, has been associated with renal tubular epithelial cell (LLC-PK1) toxicity. A study conducted by Poovala *et al.* (1999) assessed lactate dehydrogenase (LDH) release,  $\text{H}_2\text{O}_2$  levels ( $\mu\text{mol}/\text{mg}$  protein per h), and malondialdehyde formation ( $\text{nmol}/\text{mg}$  protein). Results showed LDH which significantly increased with concentration and time, after exposure of the cells to 1000, 1250, 1500, 1750 and 2000ppm of Bidrin<sup>®</sup> for 6, 12, 24 and 48h. Antioxidants 2-methylaminochroman (2-MAC) and desferrioxamine reduced cell damage induced by 1250ppm of Bidrin<sup>®</sup> over a 24h incubation. The greatest reductions in the percentage of LDH were produced by desferrioxamine 2mM and 2-MAC 2.5 $\mu\text{M}$ , both significantly lower than Bidrin<sup>®</sup> alone.  $\text{H}_2\text{O}_2$  levels were significantly elevated after exposure to 1250ppm of Bidrin<sup>®</sup>. Significantly increased malondialdehyde formation compared with control was also found in Bidrin<sup>®</sup>-exposed cells indicating enhanced lipid peroxidation. Malondialdehyde generation was significantly suppressed by 2-MAC and desferrioxamine. These results demonstrated that Bidrin<sup>®</sup> can cause direct tubular cytotoxicity, and implicate, at least in part, a role for ROS and accompanying lipid peroxidation in cytotoxicity.

#### *In vitro and in vivo protein kinase c activation by structurally diverse pesticides and chromium (VI) and cadmium (II)*

Various pesticides and transition metals induce oxidative deterioration of biological macromolecules in which

protein kinase C (PKC) may play a major regulatory role. PKC is a family of isoenzymes with distinct roles in normal and pathogenic activities within cells. PKC is involved in signaling pathways mediating the regulation of many cell processes including cell differentiation, cell survival, gene expression, secretion, cytoskeletal function, and cell–cell interactions (Lord and Pongracz, 1995). Thus PKC is involved in a cascade of events associated with cell regulation which is subject to both internal and external factors. A growing body of evidence indicates that free radicals and ROS may be involved in mediating signal transduction through interaction with PKC (Brawn *et al.*, 1995; Lander *et al.*, 1995). Studies have demonstrated that PKC is rapidly activated in cells following oxidative exposure (Brawn *et al.*, 1995). For example, the modulation of PKC activity by oxidant tumor promoters and the phorbol esters is well known (Prasad and Jones, 1992; Lord and Pongracz, 1995). The modulation of PKC by carbon tetrachloride has been shown to depend on the degree of oxidative imbalance caused by various concentrations of this haloalkane.

The comparative *in vitro* and *in vivo* abilities of structurally diverse pesticides including TCDD, endrin, chlordane, lindane, DDT, alachlor, chlorpyrifos and fenthion, and chromium (VI) and cadmium (II) to modulate protein kinase C (PKC) activity were assessed in both cultured neuroactive PC-12 cells *in vitro* and in the brain tissues of these xenobiotics-treated animals (Bagchi *et al.*, 1996a, b, 1997).

Approximately 2–3.5-fold increases in PKC activities in the brain tissues were observed as compared to the control tissues (Table 27.8). Concentration-dependent effect of these xenobiotics was observed on enhanced PKC activities (2.9- to 4.3-fold) in neuroactive pheochromocytoma PC-12 cells (Table 27.9). In these *in vitro* experiments, maximum activation of PKC was also observed primarily with 100nM concentrations of these xenobiotics. No further increases in PKC activity were observed following

**TABLE 27.8** Comparative PKC activity in female Sprague-Dawley rats following treatment with pesticides, cadmium chloride (Cd(II)) and sodium dichromate (Cr(VI)) in brain

Treatment	Protein kinase C activity/ $\mu$ g of protein/min
Control	10.7 $\pm$ 1.1 <sup>a</sup>
TCDD	25.2 $\pm$ 2.9 <sup>b</sup>
Endrin	24.4 $\pm$ 3.7 <sup>b,c</sup>
Chlordane	20.8 $\pm$ 1.7 <sup>c</sup>

Cadmium (II)	1.21 $\pm$ 0.14 <sup>d</sup>	2.95 $\pm$ 0.32 <sup>c</sup>	2.88 $\pm$ 0.30 <sup>c</sup>

Cultured cells were treated individually with 50, 100 or 200 nM concentrations of pesticides, or 0.2, 0.4 or 0.6  $\mu$ M concentration of cadmium chloride (Cd(II)) or sodium dichromate (Cr(VI)) in two equally divided concentrations at 0 and 21 h and incubated at 37°C. PKC activity was monitored using a kit from Upstate Biotechnology, NY, at the 24 h time point. Values with non-identical superscripts are significantly different ( $P < 0.05$ ).

treatment with 200 nM concentrations of these xenobiotics. Thus, organophosphate pesticides as well as other xenobiotics can modulate a vital component in the cell signaling pathway (Tables 27.8 and 27.9) (Bagchi *et al.*, 1997).

#### Developmental neurotoxicity of chlorpyrifos on cultured PC-12 and Gliotypic C6 cells

Studies have demonstrated that glial-type cells have been targeted by chlorpyrifos through the same multiple mechanisms that have been demonstrated for the effects

of chlorpyrifos on brain development *in vivo* (Garcia *et al.*, 2001). Post-neurogenesis, glial development continues and given that chlorpyrifos targets events in both glial cell replication and the later stages of differentiation, the vulnerable period for developmental neurotoxicity of chlorpyrifos is likely to extend well into childhood or even early adolescence. Early *in vitro* studies have also demonstrated the methods causing neurotoxicity by chlorpyrifos, by means of assessment of cultures of immature brain tissue (Roy *et al.*, 1998; Monnet-Tschudi *et al.*, 2000) or transformed neural cell lines, such as neurotypic PC-12 cell lines. PC-12 cell lines are less receptive to neurotoxins and have shown to effectively establish cell replication as a major target because they maintain a fixed pattern of mitosis until differentiation is triggered by addition of trophic factors and deletion of serum (Crumpton *et al.*, 2000). To demonstrate the antimitotic effects of chlorpyrifos, a study in two *in vitro* models, PC-12 cells and gliotypic C6 cells, was compared (Qiao *et al.*, 2001). In the first set of experiments, PC-12 and gliotypic C6 cells were exposed to chlorpyrifos or chlorpyrifos metabolites for 1 h in the absence of serum, to obviate any potential protective effect of serum proteins (Garcia *et al.*, 2001) selecting a chlorpyrifos concentration (30  $\mu$ M) which was previously found to cause robust but submaximal inhibition of DNA synthesis *in vitro*. Equimolar concentrations of chlorpyrifos-oxon also produced significant inhibition of DNA synthesis, again with gliotypic C6 cells showing a greater effect than PC-12 cells; however, chlorpyrifos-oxon was also significantly less effective than was chlorpyrifos itself (Monnet-Tschudi *et al.*, 2000).

The effects of chlorpyrifos were also compared with other cholinesterase inhibitors; using equivalent concentrations (30  $\mu$ M) of each compound demonstrated that both diazinon and physostigmine caused significant inhibition of DNA synthesis in gliotypic C6 cells. For PC-12 cells, diazinon caused a significant decrement, though smaller than the effect of chlorpyrifos, while physostigmine was ineffective. The current results are consistent with previous concepts where it was demonstrated that chlorpyrifos exerts antimitotic actions on developing neural cells independent of cholinesterase inhibition (Pope, 1999; Slotkin, 1999). It was also observed that chlorpyrifos was more effective than chlorpyrifos-oxon, despite the fact that the latter is a far more potent cholinesterase inhibitor.

The effects of chlorpyrifos and its major metabolites in two *in vitro* models, PC-12 cells and gliotypic C6 cells, showed chlorpyrifos inhibited DNA synthesis in both cell lines but had a greater effect on gliotypic cells. Chlorpyrifos-oxon, the active metabolite that inhibits cholinesterase, also decreased DNA synthesis in PC-12 and gliotypic C6 cells with a preferential effect on the latter. However, diazinon also inhibited DNA synthesis with predilection toward gliotypic C6 cells and was

less effective than was chlorpyrifos. It was also found that the addition of sera protected the cells from the adverse effects of chlorpyrifos and that the effect could be reproduced by addition of albumin. These results indicate that chlorpyrifos and diazinon have immediate, direct effects on neural cell replication, preferentially for glial cells. The fact that the fetus and newborn possess lower concentration of serum protein, and hence at very low concentration of chlorpyrifos the neurotoxic effect occur on them, while at the same concentration these are non-toxic to adults demonstrating the protective effect of serum proteins. (Aschner, 1999; Monnet-Tschudi *et al.*, 2000; Garcia *et al.*, 2001).

Adverse effects of chlorpyrifos on glial cell replication are of critical importance in defining the sensitive period for effects on CNS development. Glial cells provide nutritional, structural and homeostatic support essential to architectural modeling of the brain (Morita *et al.*, 1999; Barone *et al.*, 2000) and because glial development continues well into the postnatal period, glial targeting implies a prolonged vulnerability, extending into childhood. Chlorpyrifos administration *in vivo* inhibits DNA synthesis and causes loss of brain cells during gliogenesis (Dam *et al.*, 1998) with maximal effects on neural functions appearing during peaks of glial development (Monnet-Tschudi *et al.*, 2000). In aggregating brain-cell cultures, chlorpyrifos affects glial markers, again unrelated to cholinesterase inhibition. The above results thus confirm conclusively that chlorpyrifos, rather than its active metabolite chlorpyrifos-oxon, is the primary agent in these effects (Bagchi *et al.*, 2006).

Taking together, 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), endrin, chlordane, lindane, alachlor, naphthalene, Cr(VI) and Cd(II) are environmental as well as industrial pollutants, and extensive research has provided evidence that ROS and oxidative stress are involved in the toxicity of these xenobiotics in the brain tissue and other essential organs.

### Naphthalene (a bicyclic aromatic hydrocarbon)

Naphthalene (NAP) is widely used in various commercial and industrial applications including lavatory scent disks, soil fumigants and moth balls. Exposure to naphthalene is associated with the development of hemolytic anemia in humans and laboratory animals (Germansky and Jamall, 1988). The toxic manifestations induced by naphthalene appear to involve the conversion of naphthalene to the naphthoquinones as 1,2-naphthoquinone and 1,4-naphthoquinone (Lubek *et al.*, 1989) as well as hydroxylated products including 1-naphthol, 2-naphthol and 1,2-dihydro-1,2-dihydroxynaphthalene (Seaton and Tjeerdema, 1995). In general, quinones are believed to be

toxic by a mechanism involving redox cycling and oxidative stress. The role of ROS in the cytotoxicity of various quinoline derivatives has been reviewed extensively. Menadione (2-methyl-1,4-naphthoquinone) has been the most extensively studied model compound with respect to the toxicity of quinoline derivatives and naphthoquinones (Stohs, 1995).

### Naphthalene-induced membrane microviscosity

In a study by Vuchetich *et al.*, (1996), membrane fluidity studies were performed on mitochondrial and microsomal membranes of brain tissues by steady-state fluorescence spectroscopy. The membranes were treated with 0.5mM diphenyl-hexatriene (DPH) in tetrahydrofuran as the fluorescent probe and incubated for 2h at 37°C. The membranes were kept at 4°C for 3–5h for complete incorporation of DPH. Fluorescence polarization, a measure of membrane fluidity, was determined at 25°C with a Perkin-Elmer spectrofluorometer equipped with perpendicular and parallel polarizers, using an excitation wavelength of 365nm and an emission wavelength of 430nm. Fluorescence polarization and the apparent microviscosity were calculated as described by Shintzky and Barrenholz (1978) and Bagchi *et al.* (1992) (Table 27.10).

The ability of naphthalene to induce an oxidative stress was determined by measuring lipid peroxidation (TBARS), DNA-SSB, glutathione depletion and membrane microviscosities of the brain tissues. The effects of naphthalene (1100mg/kg) and/or vitamin E succinate administered to rats were assessed on lipid peroxidation in brain mitochondria and microsomes. Following naphthalene administration, maximum increases in lipid peroxidation in brain subcellular fractions were observed at the 12h time point. Increases in lipid peroxidation of 2.4- and 2.0-fold occurred at 12h post-treatment in the brain mitochondria and microsomes, respectively, as compared to control values (Bagchi *et al.*, 1998a).

The results indicate that naphthalene induces the production of ROS. The ROS produced may lead to enhanced lipid peroxidation, as well as other cell-damaging effects, including membrane and DNA damage and glutathione depletion, contributing to the toxic manifestations of naphthalene. The administration of vitamin E succinate significantly attenuates these effects following an acute dose of naphthalene in rats (Table 27.11).

In another study, low-dose (0.05 LD<sub>50</sub>) chronic effects of naphthalene (110mg/kg/day, po, in corn oil) were investigated for 120 consecutive days on increased lipid peroxidation and DNA fragmentation in brain tissues of female Sprague-Dawley rats. The results of this study demonstrated that chronic administration of naphthalene at low dose may induce oxidative stress leading to lipid peroxidation and DNA fragmentation in the brain and liver (Bagchi *et al.*, 1998a, b).

TABLE 27.10 NAP-induced changes of membrane microviscosity in the brain mitochondrial and microsomal membranes, and the protective ability of vitamin E succinate (VES)

### MYCOTOXINS, OXIDATIVE STRESS, DNA DAMAGE AND APOPTOSIS

Among all mycotoxins, aflatoxins occur with greatest frequencies contaminating animal feed. Aflatoxin B1 (AFB1) is the most toxic and is a recognized pulmonary and hepatic carcinogen. The most widely accepted mechanism of AFB1-induced carcinogenicity involves its bioactivation to AFB1-8,9-*exo*-epoxide and binding to DNA to form AFB1-N<sup>7</sup>-guanine. Another potential cause of DNA damage is AFB1-mediated excess reactive oxygen species (ROS) formation, leading to oxidation of DNA bases. Guindon *et al.* (2007) demonstrated the ability of AFB1 to cause oxidative DNA damage in lung cell types of the A/J mouse. Furthermore, the formation of 8-hydroxy-2'-deoxyguanosine (8-OHdG) in freshly isolated mouse lung alveolar macrophages, alveolar type II cells and nonciliated bronchial epithelial (Clara) cells was assessed by high-performance liquid chromatography with electrochemical detection. These results support the possibility that oxidative DNA damage in mouse lung cells contributes to AFB1 carcinogenicity.

Both AFB1 and ochratoxin A (OTA) induce oxidative stress and play an important role in the toxicity and cellular injury. The protective effect of two catechins, namely, epigallocatechin gallate and epicatechin gallate, against ochratoxin A-induced cytotoxicity was investigated in a pig kidney cell line (LLC-PK1) (Costa *et al.*, 2007). The ability of catechins to reduce ochratoxin A-induced oxidative stress and DNA damage was investigated. The free-radical scavenging capacity of both catechins was tested with the Briggs-Rauscher oscillating method and the TEAC assay. Significant reduction of ochratoxin A-induced oxidative stress and DNA fragmentation was found in cultured LLC-PK1 cells pretreated with catechins.

Elimination of AFB1 contamination in agricultural products has been difficult; the use of natural or synthetic free radical scavengers could be a potential chemopreventive strategy. Boric acid is the major component of industry and its antioxidant role has recently been reported. Turkez and Geyikoglu (2010) assessed the protective ability of boric acid following exposure to AFB1 in human whole blood cultures. The biochemical characterizations of glutathione and some enzymes have been carried out in erythrocytes. Alterations in malondialdehyde (MDA) level were determined as an index of oxidative stress. The sister-chromatid exchange and micronucleus tests were performed to assess DNA damages in lymphocytes. AFB1 treatment significantly reduced the activities of antioxidants by increasing MDA level (30.53 and 51.43%) of blood, whereas the boric acid led to an increased resistance of DNA to oxidative damage induced by AFB1 in comparison with control values ( $P < 0.05$ ). In conclusion, the support of boric acid was especially useful in AFB1-toxicated blood. Thus, the risk on tissue targeting of AFB1 could be reduced ensuring early recovery from its toxicity.

### CONCLUSIONS

Oxidative stress-related degenerative diseases constitute one of the major challenges of modern medicine and health professionals. Although these diseases are relatively common and often highly debilitating, the mechanisms responsible for their clinical pathologies are poorly understood, and there are currently no effective preventive or therapeutic strategies. Recent studies demonstrated that oxidative stress and oxidative DNA damage may be involved in the cytotoxicity of chlorpyrifos,

fenthion and other pesticides, as well as heavy metals. Reactive oxygen species (ROS) may serve as common mediators in programmed cell death (apoptosis) or non-programmed cell death (necrosis) in response to many toxicants and pathological conditions. Figure 27.3 exhibits a schematic diagram of the mechanistic pathways involved in the disease pathophysiology. Finally, much experimental evidence demonstrates that structurally diverse and dissimilar environmental pollutants including pesticides, heavy metals and mycotoxins have adverse effects on immune functions and various organs in the body. These cascades of events lead to altered gene expression and down-regulation of antioxidant defense system and cause chemical toxicity. Lowering the burden of protein aggregation, oxidative and nitrosative stress, mitochondrial injury, inflammatory response and heavy metal toxicity in the body to block chemical toxicity may prove beneficial in the treatment of several degenerative diseases due to oxidative stress and mycotoxin-induced toxicity. The economic impact of mycotoxin and other pesticide-related chemical toxicity include loss of animal and human life, increased health care and veterinary care costs, reduced livestock production, disposal of contaminated foods and feeds, and investment in research and applications to reduce severity of the above problems. Although efforts have continued internationally to set guidelines to control mycotoxins, pesticides, herbicides and metal toxicity, practical measures have not been adequately implemented.

# Toxicity of over-the-counter drugs

Karyn Bischoff and Motoko Mukai

## INTRODUCTION

The topic of over-the-counter (OTC) drugs is complicated, encompassing a large number of products, many containing multiple active ingredients. Products are available for oral, topical, intraocular, intranasal and intrarectal administration, though most veterinary exposures are through ingestion. These products are readily available in many homes. Toxicosis may result when animals are medicated by well-intentioned animal owners or even veterinarians, or exposure may be accidental, in which case the amount of medication ingested may not be known. Response to a given drug may be species specific or different between individuals of the same species. Idiosyncratic reactions to drugs must also be considered, though reports in domestic animals are rare (Papich, 1990; Brumbaugh, 2001).

Approximately a quarter of the calls to human poison control centers in 1990 dealt with OTC drugs (Murphy, 1994; Villar *et al.*, 1998). Similarly, nearly a quarter of the calls to the American Society for the Prevention of Cruelty to Animals' Animal Poison Control Center (ASPCA-NAPCC) in 2010 were for human medications, most of them OTC (<http://www.asPCA.org/pet-care/poison-control/top-10-pet-poisons-of-the-year.aspx>, accessed February 26, 2011). It is estimated that there are over 300,000 OTC drug formulations available with approximately 700 active ingredients in various combinations (Papich, 1990). Only a small fraction can be addressed in this chapter.

Important classes of drugs that will be addressed include analgesics, cold, flu and allergy medications, and drugs used to treat gastrointestinal symptoms. Nutritional supplements, for the most part, will not

be addressed here, though a few herbal preparations (ma huang and guarana) are discussed. Toxicologically important minerals such as iron and important vitamins such as vitamin D are addressed in other chapters. Stimulants and diet pills often contain methylxanthines such as caffeine, which are also addressed in appropriate chapters, or sympathomimetic amines, which are discussed later with decongestants.

Though this chapter deals mostly with drugs intended for *per os* (PO) dosing, a few other types of formulations are discussed as well.

## SUSPECTED OTC DRUG REACTIONS

Obtaining a thorough history is of great importance when dealing with suspect OTC drug-related problems (Talcott, 2006). Animal owners may not volunteer critical information. Well-intentioned pet owners sometimes administer over-the-counter drugs to treat perceived symptoms in their pets (Papich, 1990; Jones *et al.*, 1992; Villar *et al.*, 1998; Roder, 2004a; Sellon, 2006). Veterinarians may share the blame for inappropriate dosing. Chronic analgesic administration to treat orthopedic problems is a particular hazard affecting all species of animals that present to the veterinary practice.

Accidental ingestions occur when drugs are improperly stored. Careful assessment of the history can be challenging but may be critical since unexpected circumstances can arise. For example, severe clinical signs prompted euthanasia in a kitten but it was later discovered that the kitten had been allowed to play with an empty acetaminophen container (Allen, 2003).

If an adverse reaction to an OTC drug is suspected, administration of the drug should be immediately discontinued. The owner should be instructed to bring the drug container to the veterinarian as a source of information on the active ingredients, indications for use and manufacturer identification, telephone number or address. Many manufacturers have information on treatment and prognosis and, in the United States, will use the information you provide for adverse events reporting to the Food and Drug Administration (FDA), and thus should be contacted. More information on adverse event reporting can be found at the FDA website: <http://www.fda.gov/cvm/adetoc.htm>. Any material remaining in the container can be analyzed to verify that the contents are as expected (Brumbaugh, 2001). Serum, urine and gastric lavage (liver, kidney and GI content for postmortem) should also be saved for analysis if it is unclear what the animal has ingested. Early gastrointestinal decontamination is sometimes helpful in the asymptomatic animal and may involve emetics or gastric lavage, and instillation of activated charcoal and cathartics. If drugs are used topically, removal with a mild detergent bath is usually beneficial. Careful monitoring and maintenance of body temperature is required after bathing, and bath towels may be warmed by tumbling in a heated clothes drier to help prevent hypothermia.

## ANALGESICS

According to Jones *et al.* (1992), about 5% of dog- and cat-related calls to one poison control center were in response to analgesic ingestion, and nearly 80% involved dogs. Commonly used OTC analgesics include acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin, ibuprofen, naproxen and ketoprofen. Aspirin shares many properties with other NSAIDs, but will be addressed separately due to some of its unique features.

### Acetaminophen

Acetaminophen is an analgesic and antipyretic, though it does not have the anti-inflammatory properties of NSAIDs (Hjelle and Grauer, 1986). Acetaminophen is a metabolite of the historic drug phenacetin. Acetaminophen is found in a variety of over-the-counter pain relievers and is often combined with other drugs in cold, flu and allergy medications (Roder, 2004a). Common brand names in the U.S. include Tylenol and Anacin-3. Acetaminophen is sold under the name Paracetamol in Australia and Great Britain.

Acetaminophen toxicosis is most commonly reported in cats (Rumbeiha *et al.*, 1995). Clinical acetaminophen toxicosis is usually associated with a single exposure, though adverse effects as a result of multiple dosing have been reported (Hjelle and Grauer, 1986; Villar *et al.*, 1998). The most common clinical situation results from the owner medicating their animal without the benefit of a veterinarian's advice and supervision (Hjelle and Grauer, 1986; Aronson and Drobatz, 1996). One report documents severe poisoning in a kitten that had played with an empty acetaminophen container (Allen, 2003). Although the hepatotoxic effects of acetaminophen have been described in many species, the hematotoxic effects are specific to cats and dogs (McConkey *et al.*, 2009).

### Toxicity

Individual differences in sensitivity to acetaminophen are reported within species (Webb *et al.*, 2003), but the use of acetaminophen is always contraindicated in cats due to their extreme sensitivity (Jones *et al.*, 1992; Roder, 2004a; Villar *et al.*, 1998; Wallace *et al.*, 2002). Clinical signs of acetaminophen toxicosis, up to and including death, have been reported in cats at doses of 10 mg/kg (Aronson and Drobatz, 1996). However, most poisonings are associated with doses of 50 mg/kg and greater (Murphy, 1994; Allen, 2003; MacNaughton, 2003; Roder, 2004a; Sellon, 2006). Villar *et al.* (1998) reported 50% methemoglobinemia within 4 hours in cats dosed with 120 to 140 mg/kg acetaminophen, and one of four cats dosed with 143 mg/kg died. One regular acetaminophen tablet contains 352 mg of the active ingredient, and an extra-strength tablet contains 500 mg.

The recommended dose for acetaminophen in dogs is 15 mg/kg PO every 8 hours or 10 mg/kg PO every 12 hours (Plumb, 2005). Toxicosis has been reported at a dose of 46 mg/kg (Sellon, 2006), though doses of 100 mg/kg or greater are more likely to be associated with clinical signs (Jones *et al.*, 1992; Boothe, 2001; Roder, 2004a). Most dogs dosed with less than 460 mg/kg will recover (Villar *et al.*, 1998). Doses over 460 mg/kg are associated with methemoglobinemia in dogs and deaths have occurred (Schlesinger, 1995; Villar *et al.*, 1998; Wallace *et al.*, 2002). A dose of 900 mg/kg caused "fulminant liver failure" in a dog (Boothe, 2001). Doses greater than 1 g/kg (1000 mg/kg) are reported to cause unconsciousness and cyanosis within hours and death within 12 hours (Villar *et al.*, 1998).

### Toxicokinetics

After ingestion, acetaminophen is rapidly absorbed in the stomach and small intestine (Schlesinger, 1995; Wallace *et al.*, 2002). Peak plasma concentrations occur 4 hours after ingestion in cats (Rumbeiha *et al.*, 1995). Circulating acetaminophen is minimally bound to plasma

protein and is widely distributed. The therapeutic plasma concentration of acetaminophen in a dog is near 30 µg/mL, and toxicosis is associated with levels of 300 µg/mL and greater.

Metabolism of acetaminophen occurs primarily in the liver. There are three major pathways: direct glucuronide conjugation, direct sulfate conjugation and oxidation mediated by cytochrome P450 enzymes (Hjelle and Grauer, 1986; Wallace *et al.*, 2002). Acetaminophen has an available hydroxyl group. Immediate phase II conjugation is the primary route of metabolism in most species and involves glucuronide and sulfate (Dahm and Jones, 1996). Due to limitations of cat physiology, they have only about one-tenth the acetaminophen biotransformation ability of dogs (Hjelle and Grauer, 1986; Sellon, 2006). Glucuronide conjugation is the fate of 50 to 60% of a dose of acetaminophen given to either a human or dog (Aronson and Drobatz, 1996). This pathway is deficient in cats due to decreased microsomal UDP-glucuronosyltransferase enzyme activity (Wallace *et al.*, 2002).

The amount of acetaminophen that is conjugated to glucuronide in cats is dependent on dose, but is always a relatively small proportion. After an oral dose of 20, 60 and 120 mg/kg acetaminophen, only 1, 5 and 16% undergoes glucuronide conjugation, respectively (Hjelle and Grauer, 1986). Sulfate conjugation is less important than glucuronide conjugation in the disposition of acetaminophen in most species (Aronson and Drobatz, 1996; Boothe, 2001; Allen, 2003). Dogs metabolize about 10 to 20% of a given dose of acetaminophen via sulfate conjugation, but this is the most important, although still limited, pathway in cats. Again, use of this pathway is dependent on the dose of acetaminophen. After cats were dosed with 20 mg/kg, 92% of the acetaminophen underwent sulfate conjugation, but after a dose of 60 mg/kg acetaminophen, 78% was sulfated, and if the dose was 120 mg/kg, only 57% was sulfated. The sulfate conjugation pathway can be saturated due to the limited availability of inorganic sulfates (Hjelle and Grauer, 1986).

Metabolism of acetaminophen by phase I processes is relatively minimal in most species, but is very important to the mechanism of toxicity of this drug, as will be described in the following section. Cytochrome P450 oxidation increases as phase II pathways become saturated (MacNaughton, 2003; Sellon, 2006). Approximately 5% of a dose of acetaminophen undergoes oxidation by cytochrome P450s in the dog. When cats are dosed with 20 mg/kg acetaminophen, 5% undergoes oxidation, but this number increased to 10% at doses of 60 to 120 mg/kg (Hjelle and Grauer, 1986). The product of the oxidation pathway is N-acetyl benzoquinoneimine (NAPQI). NAPQI is conjugated to reduced glutathione (GSH), forming an inactive product. A second byproduct of acetaminophen metabolism, via phase I deacetylation, is para-aminophenol (PAP). PAP is rapidly conjugated to GSH or acetate

in laboratory rodents, but cats have reduced capacity for N-acetylation and dogs lack the hepatic N-acetyltransferase enzyme (McConkey *et al.*, 2009).

The byproducts of acetaminophen metabolism are excreted predominantly through the urine (MacNaughton, 2003; Sellon, 2006; Sturgill and Lambert, 1997). Less than 5% of a dose is excreted as the parent compound in humans (Wallace *et al.*, 2002). Some conjugates are eliminated in the bile (Sturgill and Lambert, 1997; Maddrey, 2005). Rate of elimination is dependent on the species and the dose. The elimination half-life of a 100 to 200 mg/kg dose of acetaminophen is 72 minutes in dogs and increases to 210 minutes when the dose is increased to 500 mg/kg. The elimination half-life in cats for a 20 mg/kg dose is 36 minutes, but the half-life for a 60 mg/kg dose is 144 minutes, and that for a 120 mg/kg dose is 288 minutes (Hjelle and Grauer, 1986). The half-life is longer in male cats compared to females (Rumbeiha *et al.*, 1995).

### Mechanism of action

Unlike NSAIDs, the therapeutic effects of acetaminophen are independent of cyclooxygenase (COX) based on its interference with endoperoxidase (Boothe, 2001). The main target organ of acetaminophen toxicity is liver in most species. Many of the toxic effects of acetaminophen are due to the formation of the metabolite NAPQI. Large doses of acetaminophen overwhelm the sulfide and glucuronide conjugation pathways and lead to increased formation of the active metabolite (Hjelle and Grauer, 1986; Dahm and Jones, 1996; Sturgill and Lambert, 1997; MacNaughton, 2003; Roder, 2004a). NAPQI is usually conjugated with GSH, as noted above. GSH stores become depleted 16 to 24 hours after exposure to acetaminophen due to oxidation and decreased production of GSH. Para-aminophenol (PAP), another reactive metabolite, has recently been implicated in the hematotoxic effect seen in cats and dogs (McConkey *et al.*, 2009).

Unlike most species, erythrocyte injury is the predominant adverse effect associated with acetaminophen ingestion in cats. It is also observed in dogs at high doses, although effects on liver predominate in dog toxicosis at lower doses. Oxidative injury to erythrocytes takes the form of methemoglobin production or Heinz body production (Rumbeiha *et al.*, 1995; Webb *et al.*, 2003; McConkey *et al.*, 2009). GSH becomes depleted in erythrocytes and hemoglobin is oxidized to methemoglobin, which cannot carry oxygen (Hjelle and Grauer, 1986; Aronson and Drobatz, 1996). Animals with 30% of their hemoglobin converted to methemoglobin show clinical signs and cyanosis (Rumbeiha *et al.*, 1995). Methemoglobinemia is reversible (Schlesinger, 1995). Methemoglobin reductase is the enzyme responsible for

converting methemoglobin to hemoglobin. Cats have less methemoglobin reductase activity than other domestic species (MacNaughton, 2003). Acetaminophen can produce methemoglobinemia in dogs as well as cats, but this change is not seen in other species (Hjelle and Grauer, 1986; McConkey *et al.*, 2009).

Heinz body formation is an irreversible change caused by the precipitation of hemoglobin (Schlesinger, 1995; Aronson and Drobatz, 1996). Heinz bodies increase red cell fragility and decrease survival time of erythrocytes, and thus may cause hemolysis and anemia. Until recently, it was believed that NAPQI binds to the sulfhydryl groups and oxidize hemoglobin (Allen, 2003). However, erythrocytes lack the enzymes to metabolize acetaminophen to NAPQI and circulating NAPQI is unlikely to be bioavailable and has only limited ability to oxidize hemoglobin. Another reactive metabolite, PAP, was found to oxidize hemoglobin *in vitro* and thus has recently been proposed as the cause of methemoglobinemia in cats and dogs (McConkey *et al.*, 2009). There are eight sulfhydryl groups on feline hemoglobin, but only four on the hemoglobin of other domestic species and two on the human molecule, making cat erythrocytes much more prone to oxidative injury (Hjelle and Grauer, 1986; Rumbeiha *et al.*, 1995; Aronson and Drobatz, 1996; Allen, 2003; Sellon, 2006).

Compared to the hematotoxic effects that predominate in cats, hepatotoxic effects predominate in dogs, mice, rats and humans (Wallace *et al.*, 2002; Sellon, 2006). Oxidative damage to hepatocytes leads to zone 3 (centrilobular) hepatocyte degeneration and necrosis (Hjelle and Grauer, 1986; Dahm and Jones, 1996; Treinen-Moslen, 2001; Wallace *et al.*, 2002). NAPQI acts as an electrophile, causing tissue damage through formation of covalent adducts with biological macromolecules (Savides and Oehme, 1985; Hjelle and Grauer, 1986; Jones *et al.*, 1993; Dahm and Jones, 1996; Sturgill and Lambert, 1997; Villar *et al.*, 1998; Zimmerman, 1999; Treinen-Moslen, 2001). Mitochondria could be the primary target for NAPQI, which is believed to alter mitochondrial functional integrity and bind to adenine nucleotides. NAPQI is also believed to bind to membrane proteins that regulate calcium homeostasis, thus increasing intracellular calcium concentrations. Cytoskeletal damage/activation of endonucleases and DNA fragmentation are proposed in the mechanism of cell death. Production of superoxide anions causing peroxidative injury occur during phase I metabolism of acetaminophen, causing oxidative stress in the cell, especially once glutathione has been depleted. Endothelial damage is the likely cause of clinical signs such as edema of the face and extremities and hemorrhage.

Factors that enhance the toxic effects of acetaminophen include glutathione depletion due to fasting (Treinen-Moslen, 2001) and induction of P4502E1, as occurs

with barbiturate exposure (Sturgill and Lambert, 1997). Cimetidine inhibits cytochrome P450s and has been used therapeutically for acetaminophen toxicosis. Young animals are sometimes less sensitive to acetaminophen toxicosis than mature animals. This is the case in children and neonatal mice, and is believed to be due to the immaturity of the mixed-function oxidase system and more rapid glutathione synthesis in these youngsters (MacNaughton, 2003).

### Clinical signs

Clinical signs of acetaminophen toxicosis are attributable to its toxic effects on erythrocytes and hepatocytes. Clinical methemoglobinemia is the most common problem in cats and can also occur in dogs. Centrilobular hepatic necrosis is more common in dogs and also occurs in other species, including cats, humans, rats and hamsters (Hjelle and Grauer, 1986).

Clinical signs in cats usually occur within a couple of hours of exposure. Anorexia and vomiting are reported in 35% of cats presenting for acetaminophen exposure, and hypersalivation is reported in 24% (Aronson and Drobatz, 1996), and commonly occurs within 2 hours of exposure (Savides and Oehme, 1985). Diarrhea occurred in 18% of cats. Mental depression is reported in 76% and usually takes place within 3 hours.

Methemoglobinemia occurs within the 4 hours of acetaminophen ingestion and is dose dependent. Cats given a dose of 60 mg/kg acetaminophen had 21.7% of their hemoglobin converted to methemoglobin, and the methemoglobin concentration in cats dosed with 120 mg/kg acetaminophen was 45.5% (Hjelle and Grauer, 1986). Clinically evident cyanosis occurs at about 30% methemoglobinemia. Fifty-nine percent of the cats in the Aronson and Drobatz (1996) study had pale or dark mucous membranes and respiratory distress, and blood was brown in 12%. Affected cats are weak and depressed (Hjelle and Grauer, 1986; Jones *et al.*, 1992; Allen, 2003) and 12% presented comatose and 18% tachycardic (Aronson and Drobatz, 1996). Hemolysis, anemia, icterus and pigmenturia have been described and are seen within 48 hours of exposure. In addition to characteristic methemoglobinemia, edema of the face and forelimbs or front paws is commonly described in affected cats. Death in cats is usually due to methemoglobinemia, but fatal liver failure can also occur. Hepatic necrosis is most commonly associated with high-dose exposures, particularly in male cats.

Dogs often vomit soon after ingesting a high dose of acetaminophen, which can serve a protective function (Schlesinger, 1995). Severe clinical signs in dogs are usually attributable to hepatic necrosis (Hjelle and Grauer, 1986; Schlesinger, 1995; Sellon, 2006). Signs commence within 36 hours of ingestion and include nausea

and vomiting, anorexia, abdominal pain and depression. Tachycardia and tachypnea have been reported (Roder, 2004a; Sellon, 2006). Mild cases usually recover in another two to three days, but severe cases progress to icterus and death, usually within four days (Murphy, 1994; Sellon, 2006).

Methemoglobinemia also occurs in dogs after ingesting high doses of acetaminophen, and is more likely to cause death than is liver failure. Methemoglobinemia usually occurs within 12 hours of ingestion, but some dogs present after 48 hours. Doses of 200 mg/kg acetaminophen PO converted 18.8% of hemoglobin to methemoglobin in dogs, and 500 mg/kg produced 51.5% methemoglobinemia (Hjelle and Grauer, 1986). Signs reported included cyanosis, brown blood, lethargy and recumbence (Schlesinger, 1995; Wallace *et al.*, 2002; MacNaughton, 2003). Hemolysis, anemia, icterus and shock have been described. Several authors report pigmenturia. Occasionally, signs of methemoglobinemia occur in acetaminophen-intoxicated dogs in the absence of clinically evident liver damage. Facial edema, edema of conjunctiva and nictitating membrane, and edema of the forelimbs or paws are observed in dogs.

### Clinical chemistry

Methemoglobinemia and hemolysis are noted, especially in cats. Whole blood exposed to air appears brown. Heinz bodies in cats and dogs are evident on blood smears stained with new methylene blue. Heinz bodies occur within three days of dosing (Webb *et al.*, 2003) and were evident in 12% of accidentally exposed cats (Aronson and Drobatz, 1996). Anemia occurred in 75% of cats (Aronson and Drobatz, 1996) and is reported in dogs (Schlesinger, 1995; Wallace *et al.*, 2002; MacNaughton, 2003). Hyperbilirubinemia occurred within 48 h of acetaminophen ingestion in cats and has been reported in dogs with hemolysis (Schlesinger, 1995; Sellon, 2006). Regeneration was apparent in one dog 11 days after acetaminophen ingestion.

Hypoglycemia, mild hyperbilirubinemia, elevated ALT, ALP, BUN, creatinine, and CK were the changes reported in a dog that had ingested phenylpropanolamine (Rumbeiha *et al.*, 1995; Webb *et al.*, 2003; Sellon, 2006). This change was reported by Aronson and Drobatz (1996) in 35% of exposed cats. Increased ALT in dogs is a direct result of toxic hepatic injury, though hypoxic injury may contribute, and occurs within 24 hours of acetaminophen ingestion. Increased aspartate transaminase (AST) and alkaline phosphatase (ALP) activities are reported. Evidence of severe liver damage includes elevated prothrombin time (PT), partial thromboplastin time (PTT) and progressively decreased serum cholesterol albumin concentrations (Sellon, 2006). Forty-one percent of cats presenting for acetaminophen

toxicosis had hypocholesterolemia and 12% had hypoalbuminemia (Aronson and Drobatz, 1996). Hemoglobinuria and hematuria have been observed in dogs and cats with acetaminophen toxicosis.

### Diagnosis and management

Diagnosis of acetaminophen poisoning is usually based on a history of clinical exposure and appropriate clinical signs. Plasma, serum and urine can be tested for acetaminophen at human hospitals and some veterinary laboratories to confirm the diagnosis. However, test results are usually not available for hours or days, and acetaminophen toxicosis presents as an emergency, thus treatment should be initiated immediately.

If the animal presents within 6 hours of ingestion, decontamination measures can be instituted to prevent further absorption. Emetics can be used in the alert animal within a couple of hours of ingestion. However, if large doses were ingested, gastric lavage of the anesthetized, intubated animal is more likely to be appropriate. Activated charcoal and a cathartic such as sorbitol are given to prevent further absorption.

Antidotal therapy must be initiated as soon as possible in animals suspected of ingesting a toxic dose of acetaminophen. Antidotal therapy involves use of sulfate sources to bind the active metabolites and enhance glutathione production. Several sulfur donors are available and include N-acetylcysteine, S-adenosyl methionine (SAME) and sodium sulfate. *N-acetylcysteine therapy is the most accepted treatment for acetaminophen toxicosis.* Additionally, antioxidants can be used to reduce methemoglobin.

N-acetylcysteine is a source of sulfhydryl groups to be used for phase II sulfate conjugation or for glutathione production (Hjelle and Grauer, 1986; Savides and Oehme, 1985; Villar *et al.*, 1998). N-acetylcysteine is hydrolyzed to L-cysteine by deacetylase enzymes and is oxidized in the liver to inorganic sulfate. Use of N-acetylcysteine promotes sulfate conjugation of acetaminophen metabolites in cats. Rumbeiha *et al.* (1995) reported a 50% decrease in the plasma half-life of acetaminophen in cats treated with N-acetylcysteine and Savides and Oehme (1985) reported an increase in the total fraction excreted as a sulfate conjugate. Cats treated with N-acetylcysteine have a more rapid recovery of blood GSH concentrations than untreated cats. N-acetylcysteine decreased the half-life of methemoglobin in the blood of cats from more than 10 hours to 5 hours and prevented anemia.

N-acetylcysteine therapy should be initiated to any suspected case of acetaminophen toxicosis, even if treatment is delayed or exposure is unconfirmed. This treatment is most effective within 8 hours of exposure. However, treatment within 24 hours decreases mortality

though liver damage often occurs. N-acetylcysteine is sold in 10 and 20% solutions. Twenty percent solutions are diluted 1:1 in normal saline or 5 to 10% dextrose solution (MacNaughton, 2003; Plumb, 2005; Sellon, 2006). An initial dose of 140mg/kg is given intravenously (IV) slowly. Alternately, the dose can be given orally if no vomiting is evident and activated charcoal has not been given recently. Doses of 70mg/kg N-acetylcysteine should be given IV or PO every 6 hours thereafter for 48 hours.

SAMe is another possible sulfate source used to treat acetaminophen toxicosis in dogs and cats. Decreased hemolysis and overall improvement were reported in treated dogs (Wallace *et al.*, 2002). Prevention of methemoglobin production in cats by SAMe has been inconsistent. The number of Heinz bodies was lower and the packed cell volume (PCV) remained higher in treated versus untreated experimental cats (Webb *et al.*, 2003; Sellon, 2006). Dogs are given 40mg/kg PO as their first dose and 20mg/kg daily for seven to nine days. Protocols recommended for cats include 180mg/kg SAMe PO every 12 hours for three days, and 90mg/kg SAMe PO every 12 hours for 14 days.

There are reports of sodium sulfate as a treatment for acetaminophen toxicosis. This protocol decreased the plasma half-life of acetaminophen in cats and increased the amount excreted as a sulfate conjugate, similar to N-acetylcysteine (Savides and Oehme, 1985). Severity and duration of clinical signs were decreased in treated animals, methemoglobin concentrations were decreased, and glutathione concentrations rebounded faster than in untreated cats (Villar *et al.*, 1998). Sodium sulfate was given as a 1.6% solution at a dose of 50mg/kg IV every 4 hours for six treatments.

Ascorbic acid and methylene blue are commonly used to reduce methemoglobin to hemoglobin. Ascorbic acid causes nonenzymatic reduction of methemoglobin, but is slow acting. Ascorbic acid is given at a dose of 30mg/kg PO every 6 hours for six or seven treatments. Methylene blue has a rapid onset, but can induce hemolytic anemia in cats, making it a risky choice. Still, methylene blue has been used successfully for short-term management of feline methemoglobinemia. Use of methylene blue concurrently with N-acetylcysteine in cats should be avoided.

Supportive and symptomatic therapy for acetaminophen toxicosis includes administration of oxygen to animals with methemoglobinemia. Transfusion or hemoglobin replacement is needed in cases of severe anemia (Murphy, 1994; Sellon, 2006). Fluid therapy is aimed at improving hydration, electrolyte balance and pH.

Cimetidine has been recommended for use in dogs and cats to inhibit acetaminophen metabolism through inhibition of cytochrome P450 enzymes. However, the doses required for enzyme inhibition are higher than doses used routinely (Sellon, 2006).

The time that elapses between exposure and treatment seems to be as, if not more, important in estimating the prognosis for survival. Most cats that survived were treated within 14 hours of exposure, though one was not treated for 24 hours. Most of the cats that were treated 17 or more hours post-exposure died. There were no differences in exposure-dose between the group of cats that died and those that survived. Cats with underlying disease may have a worse outcome than otherwise healthy cats. The survival rate in dogs is decreased if they are not treated within 72 hours (Sellon, 2006). Animals that were treated and survived usually recovered within 48 hours and were hospitalized for three days (Aronson and Drobatz, 1996).

### *Postmortem findings*

Icterus is a common finding secondary to acute hemolysis or chronic cholestasis. Centrilobular necrosis occurs commonly in dogs and has been described in cats, though necrosis is likely to be more diffuse in cats. Bile duct proliferation, vacuolar hepatocyte degeneration and mononuclear cholangitis are reported in dogs with chronic liver injury. Subcutaneous edema extends from the head along the fascial planes of the neck and thorax in some affected cats and dogs and can affect the conjunctiva (Allen, 2003).

## **Nonsteroidal anti-inflammatory drugs (NSAIDs)**

NSAIDs are defined as "compounds that are not steroidal and that suppress inflammation" (Boothe, 2001). These drugs have antithrombotic actions when taken at low doses, relieve minor pain and pyrexia at moderate doses and have anti-inflammatory effects at higher doses (Rubin and Papich, 1990; Boothe, 2001). NSAIDs are commonly used to treat orthopedic problems in dogs (Wallace *et al.*, 1990). About 8% of all human and veterinary related calls to the Illinois Poison Control Center were reported to involve NSAIDs, most commonly aspirin, ibuprofen, naproxen, piroxicam, indomethacin and phenylbutazone. Out of those calls, 70% of the nonhuman animal calls were for dogs and 25% for cats (Kore, 1990). NSAID toxicosis can be caused by a single large dose or multiple smaller doses (Albretsen, 2002).

There are more than 30 commercially available NSAIDs (Mazué *et al.*, 1982). They are classified based on their structure into the carboxylic acid group, which includes salicylic acid derivatives, acetic acid derivatives, fenamates or anthranilic acid derivatives and propionic acid derivatives, as well as the enolic acid groups. An incomplete list of NSAIDs is provided in Table 28.1.

TABLE 28.1 An incomplete list of nonsteroidal anti-inflammatory drugs

Carboxylic acid group	Enolic group
<b>Salicylic acid derivatives</b>	<b>Pyrazolone derivatives</b>
Aspirin	Azapropazone
Diflunisal	Dipyron
Salicylates	Isopyrin
	Oxyphenbutazone
<b>Acetic acid derivatives</b>	Phenylbutazone
Etodolac	
Indomethacin	<b>Oxicam derivatives</b>
Sulindac	Lornoxicam
Tolmetin	Meloxicam
Diclofenac	Piroxicam
	Tenoxicam
<b>Fenamates/anthranilic acid derivatives</b>	<b>Coxibs</b>
Flufenamic acid	Celecoxib
Meclofenamic acid	Deracoxib
Mefenamic acid	Firocoxib
Tolfenamic acid	
<b>Propionic acid derivatives</b>	
Carprofen	
Ibuprofen	
Fenoprofen	
Flurbiprofen	
Ketoprofen	
Naproxen	
Suprofen	
Tiaprofenic acid	
<b>Aminonicotinic acid derivatives</b>	
Flunixin meglumine	

The mechanism of action is similar for all drugs in this classification. However, toxicity and pharmacokinetic data vary markedly between the different compounds and species. Cats, for example, are more susceptible to salicylate toxicosis than other species (Roder, 2004a), and dogs are very sensitive to ibuprofen (Rubin and Papich, 1990). Attempts should not be made to extrapolate the therapeutic dose from one species to another (Lees *et al.*, 1991).

Individual factors also affect susceptibility to NSAIDs. Young and aged animals do not have the same metabolic capacity as mature animals. Drug excretion can be delayed in animals with poor hepatic or renal function (Lees *et al.*, 1991; Isaacs, 1996; Roder, 2004a). Dehydration and cardiac disease decrease renal circulation, slowing drug excretion and promoting renal damage. Preexisting gastrointestinal disease could predispose to ulceration when NSAIDs are used.

Various drugs interact with NSAIDs. Changes in bioavailability are by inhibition of absorption, displacement from plasma and tissue binding proteins, and competition for active renal secretion. Some drugs enhance or diminish metabolism of other drugs by hepatic cytochrome P450 enzymes. An incomplete list of possible interactions is provided in Table 28.2. NSAIDs also

TABLE 28.2 Some NSAID–drug interactions. Consult Verbeeck (1990) for more detailed information

<b>Drugs that decrease absorption of some NSAIDs</b>
Aluminum hydroxide
<b>Drugs that compete for protein binding with NSAIDs</b>
Acetazolamide
Corticosteroids
Coumarin
Digitoxin
Hydantoin
Methotrexate
Phenylbutazone
Phenytoin
Salicylates
Sulfonamides
Tolbutamide
Valproic acid
<b>Drugs that increase metabolism rate of some NSAIDs</b>
Antihistamines
Phenobarbital
Phenytoin
Rifampicin
<b>Drugs that decrease metabolism rate of some NSAIDs</b>
Anabolic steroids
Chloramphenicol
<b>Drugs that increase excretion rate of some NSAIDs</b>
Aluminum hydroxide
Magnesium hydroxide
<b>Drugs that decrease excretion rate of some NSAIDs</b>
Probenecid
Methotrexate

affect the bioavailability of other drugs. There have been reports of deaths in people using NSAIDs with methotrexate, and ibuprofen decreases renal clearance of digoxin and lithium. The diuretic effects of furosemide and bumetanide, which are mediated by prostaglandins (PG), are inhibited by NSAIDs. NSAIDs do not influence response to thiazide diuretics in this way, but decrease the hypotensive response. NSAIDs can decrease the effectiveness of angiotensin converting enzyme (ACE) inhibitors such as captopril. NSAIDs have additive effects when used together, with decreased rates of metabolism and clearance for each (Lees *et al.*, 1991; Verbeeck, 1990). NSAIDs also have additive effects when used with corticosteroids, and such mixing should be avoided.

### Toxicity

There are species differences in NSAID tolerance, as noted above. Dogs are more susceptible to ibuprofen and naproxen toxicosis than many other species (Kore, 1990; McKellar *et al.*, 1991; Isaacs, 1996). Use of these drugs in dogs should be avoided.

Ibuprofen doses greater than 5 mg/kg have been associated with adverse reactions in dogs (Villar *et al.*, 1998). Gastric lesions occurred in dogs when 8 mg/kg/day

ibuprofen is given over a 30-day period, either PO or parenterally, though clinical signs were not evident (McKellar *et al.*, 1991; Godshalk *et al.*, 1992; Boothe, 2001; Talcott, 2006). Clinical signs were evident in dogs dosed with 16 mg/kg/d for 8 weeks. Single doses of 50 to 125 mg/kg have been associated with gastrointestinal disease (Jackson *et al.*, 1991; Murphy, 1994; Talcott, 2006) and a perforating gastric ulcer was reported in a dog given a cumulative dose of 110 mg/kg ibuprofen over a period of 48 hours (Godshalk *et al.*, 1992). Doses of 175 to 250 mg/kg have been associated with acute renal failure. Serum ibuprofen concentrations less than 31 µg/mL have not been associated with clinical signs in dogs. Melena was noted with serum concentrations of 138 µg/mL.

Cats dosed with 50 mg/kg ibuprofen had gastrointestinal hemorrhage and irritation (Kore, 1990). Doses of 200 mg/kg were associated with renal failure and over 600 mg/kg caused death. A ferret that had ingested at least 347 mg/kg ibuprofen died from respiratory failure and asystole approximately 12 hours post-exposure (Cathers *et al.*, 2000).

Naproxen induced toxicosis in dogs at a dose of 5 mg/kg/day, and plasma concentrations were >50 µg/mL (Daehler, 1986; Rubin and Papich, 1990; Boothe, 2001). Severe toxicosis was produced in a Samoyed dosed with 5.6 mg/kg naproxen, presumably once per day, over a week. Common clinical signs are anemia, melena and renal and hepatic dysfunction. A perforating ulcer was described in a dog given 10 to 20 mg/kg/day naproxen for several weeks (Daehler, 1986). Doses of 15 mg/kg/day are lethal in some dogs (Daehler, 1986; Gfeller and Sandon, 1991).

Horses do not appear to be sensitive to naproxen toxicosis. Horses given three times the recommended dose of naproxen for 6 weeks did not have clinical signs (Boothe, 2001). Phenylbutazone is commonly used in horses. The recommended oral dose is 4 mg/kg per day (Plumb, 2005). A dose of 4.4 mg/kg every 12 h over a 2-week period was associated with changes of mineralization patterns in cortical bone in growing horses from 18 to 30 months of age. This effect was reversible (Brumbaugh, 2001). The same dose has been associated with other clinical signs including CNS depression and protein-losing enteropathy. Shock was reported in one of nine horses after five days of dosing (Collins and Tyler, 1985). Therapeutic plasma concentrations for phenylbutazone in a horse range from 10 to 30 µg/mL. The therapeutic range in humans, 100 to 150 µg/mL, would be lethal in a horse (Lees *et al.*, 1991). Phenylbutazone doses of 100 mg/kg/day did not cause gastrointestinal ulcers in dogs (Mazué *et al.*, 1982).

### Toxicokinetics

NSAIDs are small, weakly acidic molecules with pK<sub>a</sub> values less than 4.5 and thus are well absorbed in the stomach (Mazué *et al.*, 1982; Kore, 1990; Rubin and

Papich, 1990; Verbeeck, 1990; Isaacs, 1996; Boothe, 2001). Peak plasma concentrations for most NSAIDs occur within 3 hours of oral dosing. Some absorption probably occurs in the proximal small intestine.

Ibuprofen is 60 to 80% bioavailable and naproxen is 68 to 100% bioavailable in dogs (McKellar *et al.*, 1991; Boothe, 2001) and blood concentrations are almost identical whether dosing is PO or IV (Runkel *et al.*, 1972). Naproxen is 50% bioavailable in horses (Boothe, 2001) and nearly 100% bioavailable in pigs (Runkel *et al.*, 1972).

NSAID distribution is variable between individual drugs and animal species. Because they are highly protein bound in the circulation, mostly to albumin, NSAIDs generally have a low volume of distribution (Brater, 1988; Verbeeck, 1990; Boothe 2001; Talcott, 2006). Protein binding in humans is 99% for ibuprofen (Brater, 1988), >99% for naproxen (Runkel *et al.*, 1972; Rubin and Papich, 1990) and 98.7% for ketoprofen (Brater, 1988). The remaining unbound fraction becomes distributed in the extracellular fluid and is responsible for the clinical effects (Brater, 1988; Kore, 1990; Boothe, 2001; Talcott, 2006). Hypoalbuminemia or displacement from protein binding sites by other drugs leads to a transient increase in the unbound fraction. Though this unbound drug is normally rapidly excreted, clinical effects may become evident. NSAIDs can partition into lipid, allowing them to cross cell membranes.

Metabolism of NSAIDs takes place primarily in the liver. Most undergo cytochrome P450 mediated oxidation to increase water solubility. Phenylbutazone is converted to oxyphenbutazone, which is similarly potent, via phase I hepatic metabolism (Lees *et al.*, 1991). Phase I metabolites and, in the case of carboxylic acid group NSAIDs, the parent compound can undergo phase II reactions such as glucuronide conjugation, sulfate conjugation and glutathione conjugation, which further increase water solubility and usually inactivate the drug. Acyl-glucuronide conjugation of propionic acid NSAIDs such as ibuprofen and naproxen is reversible and these drugs deconjugate if excretion is delayed.

Drug elimination is dependent on compound and animal species. Animals less than 6 weeks old and geriatric animals usually metabolize drugs more slowly, and hepatic or renal failure further delays elimination. High plasma protein binding also slows excretion. Plasma clearance is biphasic, with a rapid initial decline as the drug is distributed to the tissues, and then a slower decline as it is metabolized and excreted, terminating drug activity (Lees *et al.*, 1991). Less than 1% of a dose of naproxen or ketoprofen is eliminated unchanged, and approximately 1% of a given dose of ibuprofen is excreted in the urine as the parent compound (Brater, 1988). Urinary excretion is pH dependent and tends to be more rapid in alkali urine due to ion trapping.

Fecal elimination through biliary excretion is important for ibuprofen and naproxen in dogs (Runkel *et al.*,

1972; Gfeller and Sandon, 1991; Isaacs, 1996; Talcott, 2006). Half of a given dose of naproxen is eliminated in the bile of dogs (Runkel *et al.*, 1972). Drugs eliminated in the bile, such as ibuprofen and naproxen, as well as indomethacin, piroxicam, flunixin, tolafenamic acid, meclofenamic acid and diclofenac, undergo enterohepatic circulation in dogs. This prolongs the plasma half-life and is likely the cause of increased susceptibility of dogs to these compounds.

The plasma half-life of ibuprofen is 2.5 to 6 hours in dogs and cats, and 1 hour in rats (Mazué *et al.*, 1982; Lees *et al.*, 1991; Boothe, 2001). The half-life for naproxen in plasma is 35 hours in beagles (Runkel *et al.*, 1972), 74 hours in mixed-breed dogs (Isaacs, 1996), 5 hours in horses (Lees *et al.*, 1991; Isaacs, 1996), 4.8 hours in cows (Lees *et al.*, 1991), 4.8 hours in minipigs, 1.9 hours in rhesus monkeys and 8.7 hours in guinea pigs. Elimination of phenylbutazone in dogs appears to follow zero-order kinetics (Lees *et al.*, 1991). The plasma half-life for phenylbutazone is between 5 and 8 hours in horses, 37 hours in cattle and 4 hours in swine.

### Mechanism of action

The basic mechanism of action of NSAIDs is inhibition of cyclooxygenase (COX) enzymes. These enzymes are found in all cells except mature erythrocytes (Kore, 1990; Boothe, 2001). Arachidonic acid, a 20-carbon unsaturated fatty acid, is released from the cell membrane by phospholipase A<sub>2</sub> and phospholipase C when a cell is damaged. Carprofen causes moderate inhibition of these phospholipases (Lees *et al.*, 1991; McKellar *et al.*, 1991). Though arachidonic acid itself has little activity, it can enter two pathways: the COX pathway, which produces eicosanoids, or the lipoxygenase pathway, which produces leukotrienes. Oxidation of arachidonic acid by COX and further metabolism by other enzymes leads to the production of various prostaglandins (PGs) and release of oxygen free radicals (Lees *et al.*, 1991; Boynton *et al.*, 1998). These PGs include PGH<sub>2</sub>, PGE<sub>2</sub> and PGI<sub>2</sub>. With the addition of prostacyclin synthase, PGF<sub>2α</sub> is formed, and thromboxane synthase is needed for production of thromboxane A<sub>2</sub>.

PGE<sub>2</sub> and PGI<sub>2</sub> have similar actions, though the effects of PGI<sub>2</sub> tend to be of shorter duration. PGE<sub>2</sub>, which is secreted by the gastrointestinal mucosa and at other sites, causes smooth muscle relaxation and vasodilation, which enhances blood flow to the kidneys and gastric mucosa, and increases vascular permeability. It inhibits gastric acid production, inhibits pepsin production, increases gastric mucus synthesis and is believed to mediate repair and turnover of gastric epithelium (Collins and Tyler, 1985; Boynton *et al.*, 1988; Wallace *et al.*, 1990). PGE<sub>2</sub> is also found in inflammatory exudate and enhances pain response due to bradykinin and histamine. PGI<sub>2</sub> also inhibits platelet aggregation.

NSAIDs bind the active site of COX, usually through competitive inhibition, though aspirin binds platelet COX irreversibly (Rubin and Papich, 1990). There are two isoforms of COX, designated COX<sub>1</sub> and COX<sub>2</sub>. COX<sub>1</sub> is found in almost all tissues, including the gastrointestinal tract, platelets, endothelium and kidneys, is continuously produced and functions in tissue homeostasis. Most of the adverse effects associated with NSAID use are due to inhibition of COX<sub>1</sub>. Inhibition of PGE<sub>2</sub> promotes production of gastric acid and pepsin, and decreases the ability of the mucosa to secrete mucus glycoproteins and bicarbonate and respond to injury. Impairments to mucosal circulation due to loss of PG activity produce mucosal hypoxia and thrombosis.

Loss of the vasodilative actions of PGE<sub>2</sub> and PGI<sub>2</sub> in the kidneys through inhibition of COX<sub>1</sub> leads to hypoxic renal injury (Isaacs, 1996; Rubin and Papich, 1990). Production of PGs by the kidneys is relatively low, and the renal effects of acute NSAID toxicosis are seldom reported in the veterinary literature (Rubin and Papich, 1990; Talcott, 2006). Renal pathology is more often associated with chronic NSAID use. Renal papillary necrosis is frequently seen in horses, and is often associated with chronic phenylbutazone use (Gunson, 1983; Rubin and Papich, 1990). This lesion is also reported in cats, dogs, mice, rats, gerbils, hamsters, rabbits, desert mice, primates and pigs (Brix, 2002). Renal failure in cats administered meloxicam first parenterally and then orally has been recently reported (Dyer *et al.*, 2009).

Recent evidence suggests that low doses of NSAIDs cause degeneration of medullary interstitial cells and later damage to vascular endothelium, leading to microvascular thrombosis and hypoxia. Higher doses produce more rapid endothelial damage (Brix, 2002). Dehydration is a major predisposing factor for renal papillary necrosis. Dehydration commonly occurs with gastrointestinal disease, diuretic use, anesthesia, surgical stress, hemorrhagic shock or sepsis. Other risk factors described for dogs include advancing age, congestive heart failure, hepatic cirrhosis, preexisting renal problems, hypotension and concurrent administration of nephrotoxic drugs such as gentamicin or amphotericin.

COX<sub>2</sub> is produced by macrophages, fibroblasts, chondrocytes, endothelial cells and some other cell types (Roder, 2004a). This isoform only functions intermittently and is induced by cytokines in areas of inflammation (Isaacs, 1996; Roder, 2004a; Talcott, 2006). Inhibition of this enzyme produces antipyretic, analgesic and anti-inflammatory effects of NSAIDs.

Most NSAIDs inhibit both isoforms of COX, but a new class of COX<sub>2</sub>-specific NSAIDs was developed as a safer alternative. These drugs include celecoxib, deracoxib, rofecoxib, diclofenac, etodolac, firocoxib, flosulide and meloxicam. However, rofecoxib (Vioxx®) was voluntarily withdrawn from the market in 2004 due to increased risk

of adverse cardiovascular events in humans, and controversies still exist whether other compounds of this class pose a similar risk. Selectivity is species specific, and thus these new drugs sometimes cause COX<sub>1</sub> inhibition in domestic species (Talcott, 2006). Dogs treated with deracoxib and firocoxib did have fewer clinical signs and gastric lesions than dogs treated with other NSAIDs in one study (Senello and Leib, 2006). Interestingly, carprofen is COX<sub>2</sub> specific in dogs but not in humans (Talcott, 2006).

Leukotrienes (LTs) are also produced from arachidonic acid via the lipoxygenase pathway. 5-Lipoxygenase produces LTA<sub>4</sub> which is converted to LTB<sub>4</sub>, LTC<sub>4</sub>, LTD<sub>4</sub>, LTE<sub>4</sub> and others. LTB<sub>4</sub> is an important chemoattractant for neutrophils. Various LTs cause vasoconstriction, bronchospasm and increased vascular permeability (Boynton *et al.*, 1988; Strøm and Thomsen, 1990; Lees *et al.*, 1991). Some NSAIDs inhibit lipoxygenase. It has been found that in dogs, flunixin is a more potent inhibitor of LTB<sub>4</sub>-mediated neutrophil migration than phenylbutazone, which is more potent than indomethacin. Alternately, some NSAIDs actually increase LT production due to increased availability of arachidonic acid not entering the COX pathway.

NSAIDs can also inhibit phosphodiesterase. Phosphodiesterase breaks down cyclic AMP (cAMP). Increased intracellular cAMP can stabilize lysosomal membranes in polymorphonuclear leukocytes, inhibiting release of inflammatory products (Kore, 1990). Other effects of NSAIDs include inhibition of phosphatidylinositol 3'-kinase Akt signaling, important in cytokine pathways and cell regulation, mitogen-activated protein kinases involved in cell regulation, peroxisome proliferator-activated receptors, NF $\kappa$ B and heat shock proteins involved in transcription. NSAIDs also uncouple oxidative phosphorylation and thus inhibit cellular energy production (Little *et al.*, 2007).

Some NSAIDs have topical irritant properties. As weak acids, they partition to the gastric mucosa leading to decreased hydrophobicity of mucus and thinning of the mucus barrier, allowing gastric acid to penetrate to the epithelial layer. NSAIDs frequently cause mild and transient liver damage associated with cholestasis and increased liver enzymes (Boynton *et al.*, 1988; Isaacs, 1996; Roder, 2004a). More severe problems, such as hepatic necrosis, are rare. Hepatotoxicity is uncommon with ibuprofen in dogs. More commonly reported in dogs is idiosyncratic hepatotoxicosis due to carprofen (Albretsen, 2002; Roder, 2004a; Talcott, 2006). Approximately one third of these cases were in Labrador retrievers.

Cartilage degeneration has been reported in mice given aspirin, phenylbutazone, indomethacin, ibuprofen and naproxen (Isaacs, 1996). Anaphylactic reactions have been reported, but hypersensitivity to NSAIDs is rare. This problem is less common in domestic animals, but

has been documented in dogs due to phenylbutazone administration (Rubin and Papich, 1990; Lees *et al.*, 1991; Isaacs, 1996).

### Clinical signs

The most common clinical signs of NSAID overdose in all species are due to gastric mucosal irritation and ulceration. NSAIDs are capable of producing peptic ulcers in animal models (Carson and Strom, 1988). Clinical signs do not always correlate well with the severity of the lesion, probably due to the analgesic effect of NSAIDs. The asymptomatic ulcer rate among NSAID users is estimated at 50% (Isaacs, 1996). Emesis is frequently observed and the vomitus sometimes contains blood. Anorexia, diarrhea, melena and abdominal pain or colic are often noted. Animals with gastric perforations usually present with a distended abdomen due to effusion, dehydration, pyrexia, collapse, pallor and abdominal pain (Godshalk *et al.*, 1992; Talcott, 2006).

Lower gastrointestinal tract effects can include protein-losing enteropathy, most common in horses, and stricture formation. Horses with hypoproteinemia often have secondary edema (Collins and Tyler, 1984, 1985). Endotoxemia and shock have been noted in horses secondary to gastrointestinal ulceration.

Analgesic nephropathy occurs in humans and has been reported in dogs given naproxen and more recently in cats on meloxicam therapy (Isaacs, 1996; Boothe, 2001; Dyer *et al.*, 2009). Chronic use of NSAIDs in high doses appears to be a predisposing factor. Clinical signs are evident after 2 weeks or many months of chronic dosing or, sometimes, after single very high doses. Acute onset of oliguric renal failure has been described (Kore, 1990; Villar *et al.*, 1998; Roder, 2004a). Animals may present with polyuria and polydipsia, dehydration, oral ulceration and uremic coma (Mazué *et al.*, 1982).

Hepatotoxicosis is not common in NSAID-intoxicated small animals, though it has been reported in a dog given naproxen (Kore, 1990; Lees *et al.*, 1991; Isaacs, 1996) and as an idiosyncratic reaction to carprofen (Albretsen, 2002). Clinical signs include anorexia and weight loss, vomiting, lethargy, icterus, ascites and coagulopathy. Increased bleeding times are rarely reported in domestic animals (Murphy, 1994). Prolonged gestation and teratogenesis have been seen experimentally (Lees *et al.*, 1991).

### Clinical chemistry

Approximately one quarter of gastroduodenal ulceration cases in dogs present with microcytic hypochromic anemia due to chronic blood loss (Stanton and Bright, 1989). Acute blood loss is uncommon. Individuals with acute blood loss present with rapid deterioration, normocytic and normochromic anemia, a normal albumin to globulin ratio and evidence of regeneration (Stanton and Bright,

1989; Wallace *et al.*, 1990). Peracute hemorrhage is rare and occurs if a mesenteric blood vessel is eroded in the area of ulceration. Such a complication would be rapidly lethal and not allow time for a regenerative response. Increased PCV has been seen in horses with dehydration secondary to diarrhea (Collins and Tyler, 1985).

Fecal occult blood is unreliable. It can be negative for low-level blood loss or positive if red meat was fed within 72 hours of testing (Talcott, 2006). Hypoalbuminemia has been observed with gastrointestinal ulcers and protein-losing enteropathy secondary to NSAID use. Both albumin and globulin concentrations are decreased. Coagulation profiles reveal poor platelet aggregation, thrombocytopenia and increased bleeding times.

Serum chemistry reveals increased ALT, AST, ALP and bilirubin (Albretsen, 2002; Roder, 2004a). A mild, transient rise in liver enzymes often occurs during the first week of NSAID administration. Elevated blood urea nitrogen (BUN) indicates nephropathy. Phosphorus, calcium and potassium are usually also elevated. Animals with renal damage due to NSAIDs present with isosthenuria, hematuria and proteinuria. Ketonuria and pyuria have also been reported. Horses on chronic high-dose phenylbutazone therapy had normal lymphocyte counts with a left shift due to neutrophil loss into the gastrointestinal tract. Increased serum glucose concentrations were attributed to endotoxemia. Hypokalemia and hyponatremia are commonly seen in horses with diarrhea (Collins and Tyler, 1985).

### Diagnosis and management

Diagnosis of NSAID toxicosis is often based on history and clinical signs. Serum or plasma testing for NSAID drugs is available at many veterinary laboratories and human hospitals. Serum drug concentrations are unlikely to be useful in management, but some reference values are listed in the toxicokinetics portion of this section.

Endoscopy is the most sensitive test for gastric ulceration, though occasionally the ulcer will not be visible. Anesthesia is required, thus the patient must be stabilized. Survey radiographs are not usually useful. If there is gastrointestinal perforation, then poor visualization of serosal surfaces, peritoneal effusion, free gas in the peritoneal cavity and intestinal ileus are often noted (Godshalk *et al.*, 1992; Talcott, 2006). Large ulcerations have been identified on contrast radiographs. However, if perforation is present, barium sulfate will complicate peritonitis, thus a water soluble agent is preferred. Ulcers can be detected using ultrasound in an animal given water by stomach tube. The gastric wall is thickened with a loss of the normal five-layer structure, disruption of the mucosa and gas bubble formation. Increased fluid in the abdomen is seen in the case of peritonitis due to perforation.

Renal papillary damage can be diagnosed in humans, horses and foals using ultrasound (Brix, 2002; Roder, 2004a). Computed tomography has been used to diagnose renal papillary necrosis in humans, and magnetic resonance imaging has been used experimentally (Brix, 2002).

Animals on NSAID therapy should be closely monitored for adverse effects. Attitude, appetite, hydration, electrolyte status, urine concentrating ability, urine protein concentrations, BUN, creatinine and liver enzymes can be examined (Villar *et al.*, 1998; Roder, 2004).

When animals present with adverse effects attributable to NSAIDs, administration of the drug should be discontinued. Gastric emptying is appropriate for animals that have ingested large quantities of NSAIDs but are not yet showing clinical signs (Kore, 1990). Emetics are sometimes used for large single ingestions, though they are contraindicated in animals with severe CNS suppression. Gastric lavage can be performed in the anesthetized, intubated animal (Cathers *et al.*, 2000). Activated charcoal and cathartics are given after gastric emptying or if the animal presents later. Repeated activated charcoal administration is recommended for various reasons. Some tablets are sustained release, and regular tablets can form concretions in the stomach and have delayed absorption. Furthermore, activated charcoal prevents enterohepatic cycling which is the cause of a prolonged half-life of ibuprofen and other NSAIDs in dogs.

Animals should be monitored for hydration, electrolyte imbalances, acid-base imbalances, blood glucose, liver enzymes, BUN and creatinine, body temperature and blood pressure. Deviations from expected values can be corrected as needed. Fluid therapy is needed to correct dehydration, hypotension, electrolyte imbalances and improve renal perfusion. It has been suggested that fluids be given at twice maintenance rates. Villar *et al.* (1998) recommend 0.9% saline, or 0.45% saline plus 2.5% dextrose in hypoglycemic animals, given at a rate of 120 mL/kg/day plus estimated fluid losses, over a 48- to 72-hour period. Lactated Ringers solution can contribute to electrolyte imbalances and thus should be used with caution. Dopamine at a dose of 2.5 µg/kg/minute or dobutamine at 2.5 mg/kg/minute is given to increase renal perfusion (Kore, 1990). Diuretics can predispose animals to dehydration and subsequent renal hypoperfusion and thus should be avoided (Albretsen, 2002). Sodium bicarbonate is used to treat acidosis (Murphy, 1994; Roder, 2004a). Urine alkalization for ion trapping is sometimes useful with salicylates, aspirin and ibuprofen, but urinary pH must exceed 7.5 to 8 to increase naproxen secretion. Urine alkalization must be used with caution to prevent metabolic alkalosis.

Gastric lavage with iced saline or water has been recommended for severe and continued gastric bleeding, but the efficacy of this treatment is questionable and surgical correction is often required in cases of refractory

bleeding (Wallace *et al.*, 1997). Severe anemia is treated with transfusions or use of blood substitutes (Murphy, 1994; Sellon, 2006). Acute loss of greater than 30% of the blood volume, a PCV less than 20%, plasma protein less than 3.5 g/dL or continued blood loss are possible indications for transfusion (Talcott, 2006). Vitamin K<sub>1</sub> is given to aid coagulation (Kore, 1990). Perforating ulcers must be managed surgically.

Gastrointestinal protectants are typically used in NSAID overdose cases to prevent or heal gastric ulcerations. Gastric pH must be maintained above 3 for 18 to 20 hours a day for effective healing, and above 4 in critically ill patients. Gastric pH above 4 inhibits fibrinolysis and the activity of pepsin. Gastric pH must be above 6 to promote platelet aggregation and prevent clot dissolution, therefore allowing hemostasis. Gastric secretion is variable in beagles, which have a median pH of 1.30 under normal conditions and 4.44 if fasted (Bersenas *et al.*, 2005). Therefore, simply withholding food has the benefit of decreasing gastric acid secretion and minimizing emesis.

Treatment with antacids such as magnesium hydroxide (milk of magnesia) or aluminum hydroxide is probably adequate for animals exposed to low NSAID doses. Antacids require dosing every 2 to 4 hours and sometimes produce changes in fecal consistency (Wallace *et al.*, 1990). Products containing bismuth subsalicylate (Pepto Bismol and Kaopectate) should be avoided because salicylate is an NSAID.

Misoprostol is a long-lasting synthetic analog of PGE<sub>1</sub>. It is the only agent that consistently prevents and treats NSAID-induced gastric and duodenal ulcers (Isaacs, 1996). When given concurrently with aspirin, misoprostol prevented gastric ulcers in dogs (Villar *et al.*, 1998). Dogs given NSAIDs and misoprostol had less gastrointestinal hemorrhage, less vomiting and less mucosal ulceration on endoscopy than dogs given NSAIDs only (Talcott, 2006). Misoprostol is believed to protect renal function in domestic animals and be chondroprotective in pigs (Isaacs, 1996). At high doses, misoprostol can cause diarrhea and use of this synthetic prostaglandin is contraindicated in pregnant animals (Villar *et al.*, 1998). Dogs may be given 1 to 5 µg/kg misoprostol PO every 8 hours (Plumb, 2005).

Proton pump inhibitors suppress gastric acid secretion by inhibiting the H<sup>+</sup>/K<sup>+</sup>-ATPase pump in gastric parietal cells (Walan *et al.*, 1989; Villar *et al.*, 1998). Omeprazole and pantoprazole are proton pump inhibitors (Bersenas *et al.*, 2005). Omeprazole has been used successfully in humans and dogs to treat gastric ulcer. Bersenas *et al.* (2005) found 2 mg/kg omeprazole PO given to dogs twice per day kept their gastric pH from going below 3 for 90.9% of the day, and kept the gastric pH above 4 for 78.3% of the day, though one in six dogs vomited. Omeprazole remains biologically

active for nearly 24 hours and only need be given once daily. Plumb (2005) lists the canine daily dose as 0.5 to 1.0 mg/kg PO, and the feline dose as 0.7 mg/kg. Villar *et al.* (1998) recommend a 3- to 4-week treatment protocol. Rebound acid secretion has been reported at discontinuation of omeprazole therapy (Driman *et al.*, 1995).

Sucralfate is an aluminum salt of sucrose sulfate. This drug complexes with exposed proteins on the surface of gastric ulcers, specifically fibrinogen and albumin, and acts as a direct mucosal protectant. Sucralfate has five times as much affinity for damaged mucosa as it does for normal mucosa (Villar *et al.*, 1998). Sucralfate also adsorbs pepsin and bile acids. This drug is believed to promote bicarbonate and mucus secretion by the gastric mucosa. Sucralfate is equally as effective as cimetidine at reducing discomfort and promoting ulcer healing. Dogs given sucralfate to treat gastric ulcers, with and without concurrent cimetidine treatment, had completed healing of the gastric mucosa within nine days of treatment. Sucralfate can be used alone if gastric hyperacidity is not suspected (Wallace *et al.*, 1990). If used with cimetidine, dosing should be staggered or cimetidine should be given by a parenteral route. Sucralfate interferes with absorption of cimetidine from the gastrointestinal tract (Wallace *et al.*, 1990). Cimetidine should be given 1 hour before a meal. Dogs are dosed every 8 hours and dogs weighing >20 kg are given 1 g per dose, and smaller dogs are dosed with 0.5 g (Murphy, 1994; Albrechtsen, 2002; Plumb, 2005). Cats are given a total of 0.25 to 0.5 g every 8 to 12 hours and ferrets are given 75 mg/kg four to six times a day, preferably 10 minutes before feeding. Foals are given 1 to 2 grams PO two to three times daily.

H<sub>2</sub> histamine receptor antagonists, including cimetidine, ranitidine and famotidine, are routinely used to treat NSAID-induced gastric ulcers. Histamine stimulates gastric parietal cells to secrete hydrogen ions through an H<sup>+</sup>/K<sup>+</sup>-ATPase pump. Acetylcholine, gastrin and histamine stimulate this proton pump. H<sub>2</sub> inhibitors only block the histaminic effect on parietal cells, but cause significant inhibition of gastric acid secretion nonetheless (Bersenas *et al.*, 2005). H<sub>2</sub> inhibitors are likely to suppress clinical signs associated with unhealed ulcers (Talcott, 2006).

Cimetidine has been commonly used to treat and prevent NSAID-induced ulcers. Cimetidine is believed to decrease gastrointestinal discomfort and does decrease gastric acid secretion (Boulay *et al.*, 1986; Isaacs, 1996). Cimetidine has not been proven to be effective with continued NSAID use and did not prevent gastric ulcer formation when used concurrently with aspirin. Cimetidine is more useful when NSAID administration has ended and could be helpful if given after a single large dose (Kore, 1990). Gastric acid production is dependent on local circulation, which provides oxygen and energy. Cimetidine decreases gastric blood flow, which

contributes to decreased mucosal alkalinity (Cheung and Sonnenschein, 1983). Reduced circulation also contributes to tissue hypoxia. Cimetidine is known to inhibit hepatic cytochrome P450 enzymes and therefore could decrease the rate of NSAID metabolism (Talcott, 2006; Wallace *et al.*, 1990; Verbeeck, 1990). Cimetidine given at a dose of 6mg/kg every 6 hours caused decreased basal acid output in dogs by 30 to 50% and food induced output by 63 to 71%. When 12mg/kg was used every 6 hours, there was a 70 to 80% decrease in basal acid output and complete suppression of food-induced output (Boulay *et al.*, 1986). Cimetidine is given to dogs at a dose of 5 to 10mg/kg PO, SC, or slow IV every 6 to 8 hours (Villar *et al.*, 1990; Plumb, 2005). Similar dosing protocols are used in cats and ferrets.

Ranitidine does not inhibit microsomal enzymes like cimetidine. However, Bersenas *et al.* (2005) found no significant effect on gastric acid secretion in dogs dosed with ranitidine. Ranitidine also decreases gastric blood flow. Ranitidine is given at a dose of 0.5 to 2.0mg/kg PO, IV, or IM every 8 to 12 hours in dogs, and 2.5mg/kg IV or 3.5mg/kg PO in cats every 12 hours (Plumb, 2005). Villar *et al.* (1998) recommend continuous treatment for 3 to 6 weeks.

Famotidine increases intragastric pH in dogs better than ranitidine. However, a 0.5mg/kg dose of famotidine given two to three times a day did not result in a prolonged gastric pH increase (pH > 4) in dogs (Bersenas *et al.*, 2005). Famotidine was found protective against reduced gastric perfusion when used at a dose of 0.5mg/kg IV in dogs given diclofenac (Hata *et al.*, 2005). Dogs are given 0.5 to 1mg/kg famotidine PO or slow IV every 12 hours. The dose for cats is 0.5mg/kg and 0.25 to 0.5mg/kg is the dose for ferrets. Horses are given 0.23mg/kg IV or 1.88mg/kg PO every 8 hours, 0.35mg/kg IV or 2.8mg/kg PO every 12 hours.

The prognosis for NSAID toxicosis is dependent on chronicity, dose and clinical signs (Talcott, 2006). A study by Wallace *et al.* (1990) found that seven out of seven dogs treated for chronic NSAID toxicosis recovered after two to nine days of hospitalization. The mean hospital stay was six days. Gastrointestinal irritation and ulceration are reversible, but perforation and peritonitis require intensive surgical and medical management and have a guarded prognosis. Renal effects such as nephropathy are often reversible, but papillary necrosis is a permanent change, though well tolerated in horses. Loss of the long loops of Henle decreases urine concentrating ability, but horses with renal papillary necrosis usually appear clinically normal (Gunson, 1983; Roder, 2004a). Severe acute cortical necrosis is associated with irreversible renal failure. NSAID-induced coagulopathies are reversible once the NSAID has been eliminated. Dogs with idiosyncratic hepatic injury usually recover within 4 weeks (Albretsen, 2002).

### Postmortem findings

NSAID toxicosis is most commonly associated with gastrointestinal lesions in domestic animals. Mild lesions include mucosal edema, irritation and petechiation, which progress to erosive and then ulcerative lesions. The location for gastric ulceration in the canine stomach is variable; lesions can be near the pylorus, lesser curvature of the fundus or diffuse. Duodenal ulcers and perforations have been reported in dogs, but can be influenced by predisposing factors. Perforations are reported to occur in the stomach, small intestine or colon. Ulcers that erode mesenteric vasculature are rapidly lethal.

Gastric ulcerations in the horse usually occur in the glandular mucosa adjacent to the margo plicatus (Collins and Tyler, 1984, 1985; Roder, 2004a). Linear circular erosions were reported in the duodenum of horses dosed with phenylbutazone, and ulcers and erosions were found throughout the small intestines. Ulcerative colitis of the right dorsal colon is commonly seen in horses with NSAID toxicosis. Fibrinonecrotic typhlocolitis was reported by Collins and Tyler (1985).

Papillary necrosis occurs with long-term NSAID administration (Mazué *et al.*, 1982). The lesion is bilateral and the papillae are cavitated, yellow-green to orange and demarcated from the medulla by hemorrhage. The lesion is most severe at the poles. Microscopically, the papilla has undergone coagulative necrosis with dilation of the collecting ducts and loops of Henle. Interstitial fibrosis extends through the medulla and cortex in chronic cases (Gunson, 1983). This lesion has been reported in horses, dogs, cats, mice, rats, gerbils, hamsters, rabbits, desert mice, primates and pigs (Brix, 2002). The lesion is common in horses given phenylbutazone, but has also been reported with flunixin, aspirin and dipyrone (Gunson, 1983). Papillary necrosis occurred in two of five dogs dosed with piroxicam (Talcott, 2006).

Interstitial nephritis, with multifocal or diffuse infiltrates of lymphocytes, has been reported, as has vacuolar degeneration of proximal and distal convoluted tubules (Kore, 1990). Tubular nephritis with epithelial necrosis and regeneration has also been described (Mazué *et al.*, 1982). Acute cortical necrosis due to NSAID toxicosis has been documented (Jones *et al.*, 1992).

Lymphoid necrosis has been noted in dogs and a ferret. Mild necrosis in the white pulp of the spleen was described in the ferret (Cathers *et al.*, 2000). Depletion and necrosis of germinal centers was discovered in a dog, though circulating lymphocytes were within the reference range.

### Aspirin and other salicylates

This group, which constitutes the most extensively used over-the-counter drugs, includes acetylsalicylic acid, or

aspirin, sodium salicylate, bismuth subsalicylate and diflunisal. Aspirin and salicylates are NSAIDs with many characteristics similar to those of other NSAIDs, as described previously. Aspirin and salicylate also have certain unique properties. Clinical toxicosis of products containing bismuth subsalicylate, an over-the-counter drug commonly used for gastrointestinal distress, are similar to those associated with other sources of salicylate, thus these products will be further discussed in this section.

Salicylates have been used since ancient times by Greek and Roman physicians Hippocrates and Galen, by South African tribes and by North American Indians. Reverend Edmund Stone wrote of the use of *Salix alba* bark in the journal of the Royal Philosophical Society in London in 1763. Salicylic acid was first isolated from the bark of willows (*Salix* spp.) and beech trees (*Fagus* spp.) in the early 19th century (Lees *et al.*, 1991). Bayer Pharmaceutical Company synthesized acetylsalicylic acid in 1893 and aspirin has been marketed since 1899.

Contraindications for aspirin use include coagulation disorders, recent (within 1 week) surgery and concurrent use with certain drugs. See Table 28.2 for a list of drugs that may interact with aspirin and other NSAIDs. Aspirin inhibits the diuretic effects of spironolactone (Verbeeck, 1990).

### Toxicity

The efficacy of aspirin is dose dependent. Aspirin is used in dogs at doses of 10 to 25 mg/kg every 8 to 12 hours for analgesia. Dogs dosed with 25 mg/kg aspirin every 8 hours for up to 3 weeks had no serious adverse effects and peak plasma concentrations were  $>50\mu\text{g/mL}$  in mature dogs (Lees *et al.*, 1991). The half-life is likely to be increased in pups less than 30 days old due to limited metabolic capability (Waters *et al.*, 1993). A study of dogs dosed with 25 to 35 mg/kg aspirin every 8 hours found increased fecal hemoglobin and gastric ulcerations were visualized on endoscopy (McKellar *et al.*, 1991). Seizures were reported on a dog given 37 mg/kg aspirin every 12 hours for 2 weeks (Schubert, 1984). Clinical signs in dogs dosed with 50 mg/kg aspirin every 12 hours included emesis. Similar daily doses were associated with perforating gastric ulcers within 4 weeks (Kore, 1990). One dose of 400 mg/kg caused hemorrhage and daily dosing caused pyloric ulcers within 2 weeks (Mazué *et al.*, 1982).

Cats are more susceptible to the toxic effects of aspirin than dogs and humans (Papich, 1990; Roder, 2004a). Doses of 25 mg/kg every two to three days are recommended to control thromboembolic disease and 10 mg/kg every other day can be used for analgesia and antipyresis (Plumb, 2005). A dose of 10.5 mg/kg aspirin every 52 hours produced plasma concentrations ranging from 50 to  $20\mu\text{g/mL}$ . No clinical signs were seen in cats dosed with 25 mg/kg aspirin every 48 hours and

no severe signs were seen in cats dosed with 25 mg/kg aspirin every 24 hours for 2 to 3 weeks (Lees *et al.*, 1991; Boothe, 2001). Aspirin doses between 100 and 110 mg/kg daily have caused death in cats within seven days (McKellar *et al.*, 1991). Young cats, old cats or cats with renal or hepatic disease are believed to be particularly sensitive (Kore, 1990).

Aspirin can be used in cattle and goats, but they require larger oral doses to reach appropriate plasma concentrations. A dose of 100 mg/kg PO given every 12 hours in cattle maintains a therapeutic concentration of  $30\mu\text{g/mL}$  (Davis, 1980; Boothe, 2001). IV dosing with 6.5 mg/kg hourly is associated with plasma concentrations of 50 to  $20\mu\text{g/mL}$ , 26 mg every 1.6 hours yields plasma concentrations of 200 to  $50\mu\text{g/mL}$ , and 39 mg every 2 hours yields concentrations of 300 to  $50\mu\text{g/mL}$  in the plasma. Horses can be given 35 mg/kg aspirin IV according to Davis (1980). However, a single oral dose of 20 mg/kg was associated with prolonged bleeding times (Boothe, 2001).

### Toxicokinetics

Aspirin is lipophilic at acid pH, thus it is readily absorbed from the stomach and duodenum in dogs and cats (Rubin and Papich, 1990; Talcott, 2006). Aspirin is 68 to 76% bioavailable in dogs, with some variation based on the formulation (Boothe, 2001). Enteric-coated and buffered products are used in humans and dogs (McKellar *et al.*, 1991; Murtaugh *et al.*, 1993; Boothe, 2001). Buffered aspirin is more soluble and less ionized, thus slowing absorption and decreasing gastric irritation. Acid-resistant forms are more readily absorbed at the relatively alkaline pH range of the duodenum and absorption is delayed up to 12 hours (Verbeeck, 1990). Ingestion of a fatty meal can reduce aspirin bioavailability by 30% (Mazué *et al.*, 1982). Aspirin is 70% bioavailable in cattle, but absorption is relatively slow. Salicylates in bismuth subsalicylate are 97.5% absorbed in dogs and 85.4% absorbed in cats (Papich *et al.*, 1987).

Peak serum concentrations occur 4 hours after oral dosing with buffered aspirin. Peak serum concentrations are lower in immature dogs than in mature dogs after PO or IV dosing. Circulating salicylate is 72% protein bound in humans and 45% protein bound in dogs. There is more free, and therefore bioavailable, salicylate in the hypoalbuminemic animal, but the excess is rapidly eliminated (Boothe, 2001). Aspirin is rapidly distributed to most tissues, including synovial fluid, peritoneal fluid, saliva and milk. Aspirin has a lower volume of distribution in cattle compared to other domestic species (Davis, 1980).

Aspirin is rapidly hydrolyzed to salicylate by esterases in the gastrointestinal tract, liver and erythrocytes. These enzymes are less efficient in immature dogs

(Waters *et al.*, 1993). Most of the metabolism takes place in the liver. Salicylate is bioactive and responsible for most of the clinical effects of aspirin. Salicylate is conjugated to glucuronide or glycine. The glucuronide pathway is deficient in cats, limiting their elimination of salicylate. Bismuth subsalicylate is metabolized to bismuth and salicylate in the gastrointestinal tract (Boothe, 2001).

The kidneys eliminate salicylate and its glycine conjugate (Boothe, 2001). Two to 30% of a dose of aspirin is excreted as unconjugated salicylate (Verbeeck, 1990). The rate of elimination for aspirin varies with species and age (McKellar *et al.*, 1991). The elimination half-life in dogs is dependent upon the dose form. The half-life for enteric-coated products ranges from 7.5 to 12.2 hours. The elimination half-life for aspirin given IV is 2.2 to 8.7 hours (Boothe, 2001). The elimination half-life in cats is long and increases with dose. If low doses of 5 to 12 mg/kg are given, the elimination half-life is 22 to 27 hours, but the half-life for the much higher dose of 25 mg/kg is 45 hours. Salicylate is considered to have zero-order kinetics in cats (Lees *et al.*, 1991). The elimination half-life in horses is about an hour due to ion trapping in alkaline urine. Salicylates are normal components of equine urine (Boothe, 2001). The elimination half-life of salicylates in cattle is about half an hour (Lees *et al.*, 1991; Boothe, 2001). Young animals metabolize aspirin more slowly, and the elimination half-life may be prolonged in puppies less than 30 days old, piglets, kids and foals.

### Mechanism of action

The effects attributed to aspirin are mostly caused by the active metabolite salicylate (McKellar *et al.*, 1991). Salicylate inhibits COX to block PG synthesis, as described for NSAIDs. Other NSAIDs competitively inhibit COX, but salicylates permanently inactivate the enzyme by acetylating a serine residue (Kore, 1990; Rubin and Papich, 1990; Boothe, 2001; Talcott, 2006). Platelets are unable to synthesize COX. Unlike other NSAIDs, where coagulopathy resolves once the drug is eliminated, it takes about a week to resolve aspirin-induced coagulopathy.

Aspirin has a direct irritant effect on the gastric mucosa. Aspirin is an acidic drug and is taken up by the mucosal epithelium, where it becomes concentrated (Carson and Strom, 1988; Rubin and Papich, 1990; Isaacs, 1996). Aspirin inhibits oxidative phosphorylation of the gastric mucosal epithelium, thus decreasing ATP production and  $\text{Na}^+/\text{K}^+$  movement across the cell membrane and producing cell swelling and necrosis (Rubin and Papich, 1990). Disruption of ion transport allows increased  $\text{H}^+$  ion back-diffusion into the mucosa. Injury can extend into submucosal capillaries, leading to hemorrhage, inflammation and ulceration. IV dosing of cats produced gastric erosions and ulcers, confirming that

there is also a role for COX inhibition and reduced PG synthesis in the pathophysiology of gastric mucosal damage (Villar *et al.*, 1998).

Aspirin uncouples oxidative phosphorylation, as noted above. Aspirin allows penetration of  $\text{H}^+$  across the mitochondrial membrane, thus disrupting the proton gradient. The result is inhibition of the enzyme ATP synthetase. Energy that would go into ATP production is dissipated as heat. When oxidative phosphorylation is inhibited systemically, the result is elevated body temperature (Roder, 2004a).

Salicylates can produce acidosis and increase the anion gap. Salicylate and metabolites thereof increase the anion gap directly (Schubert, 1984; Kore, 1990). Anaerobic metabolism compensates for the reduced ATP production when oxidative phosphorylation is inhibited, producing metabolites such as lactic acid, pyruvic acid and ketones, contributing to acidosis. Aspirin is also believed to directly stimulate respiratory centers in the CNS, causing hyperventilation and respiratory alkalosis, and promoting renal secretion of bicarbonate (Kore, 1990; Boothe, 2001). Later in the progression of the toxicosis, CNS suppression can decrease the respiratory rate, also contributing to acidosis.

### Clinical signs

Similar to other NSAIDs, gastric irritation is the most common side effect of aspirin. Vomiting, gastric ulceration and hemorrhage are often observed. Depression is also seen in aspirin toxicosis in dogs and cats (Kore, 1990; Jones *et al.*, 1992). Profound depression has been reported in dogs given high doses of aspirin. Dogs collapse or appear too weak to stand. Restlessness progressing to tremors, seizures and eventually coma has been observed in dogs (Kore, 1990). One dog had a progressive increase in seizure duration from 5 to 45 minutes (Schubert, 1984). Seizures and coma have also been observed in cats (Jones *et al.*, 1992; Isaacs, 1996). Seizures have been attributed to hypoventilation, acidosis and hypoglycemia. Aspirin toxicosis can cause hyperthermia in children and cats. There can be an initial hyperpnea in acute aspirin toxicosis due to stimulation of respiratory centers.

### Clinical chemistry and postmortem findings

Metabolic acidosis and increased anion gap have been noted in acute aspirin toxicosis (Roder, 2004a). Other changes are similar to those described with other NSAIDs. Bone marrow suppression can cause anemia in cats (Kore, 1990; McKellar *et al.*, 1991). Lesions similar to other NSAIDs are expected on necropsy. Gastric mucosal lesions have been documented in the pyloric antrum, body and cardiac region of the stomach of dogs (Boulay *et al.*, 1986).

### Management

Diagnosis and treatment of salicylate toxicosis is similar to that described above for NSAIDs. Urine and plasma testing is available at many veterinary and hospital laboratories but there is a poor correlation between plasma salicylate levels and with clinical signs (Talcott, 2006). The presence of salicylate in horse urine is expected, even in horses not given aspirin, and is therefore not a significant finding (Boothe, 2001).

Salicylates can inhibit gastric emptying and gastrointestinal absorption is prolonged with enteric-coated tablets, therefore, gastric lavage is sometimes useful up to 12 hours after exposure. Activated charcoal is most useful within 2 hours of aspirin ingestion. Cathartic use does not appear to decrease absorption.

Forced alkaline diuresis is more useful for aspirin than for other NSAIDs, and is frequently used by physicians. Low urinary pH promotes salicylate elimination by trapping the ionic form in the urine. Alkaline peritoneal dialysis has been recommended for large overdoses (Davis, 1980; Kore, 1990). Acetazolamide, a carbonic anhydrase inhibitor, can be used to alkalinize urine but will exacerbate metabolic acidosis. Acid-base status must be closely monitored in any animal undergoing alkaline diuresis. Monitoring and supportive care for changes in hydration, electrolyte balance and body temperature are warranted. Clearly, use of NSAIDs to treat hyperthermia must be avoided. Diazepam can be used for seizure management.

## COLD, COUGH AND ALLERGY MEDICATIONS

Medications for the symptomatic relief of cold, flu and allergies are common and can contain multiple active ingredients, including analgesics, decongestants, antihistamines, antitussives and expectorants. Other possible ingredients are ethanol and caffeine. These medications can come in a variety of forms, including oral tablets, extended-release tablets, dissolving granules/tablets and as syrup (liquid).

Dextromethorphan is a centrally active antitussive. Structurally similar to opioids, it acts on receptors in medullary cough centers and directly suppresses its activity. Due to its dissociative effects at high doses, increasing illicit use of dextromethorphan as a recreational drug has been reported (Romanelli, 2009). This effect is similar to those of ketamine and phencyclidine, which are both controlled substances discussed in the next chapter. However, dextromethorphan toxicoses are rare in small animals, sedation being the most common effect, and respiratory suppression is unlikely. If an

animal is overdosed with dextromethorphan, activated charcoal can be given early. Treatment consists of observation and supportive and symptomatic care as needed.

Guaifenesin, or glyceryl guaiacolate, is the most common expectorant or mucolytic agent. It is used as a sedative and muscle relaxant at high parental doses in veterinary medicine as an adjunct to anesthesia and for controlling seizures. Mild decrease in blood pressure, increase in cardiac rate and thrombophlebitis are possible side effects of parental exposures (Plumb, 2005). However, it is present in relatively small concentrations in over-the-counter products, and overexposure through oral route will most likely cause only minimal effects such as vomiting and gastritis. Treatment for guaifenesin overdose would include early routine detoxification (emesis is likely to be contraindicated), and symptomatic and supportive care (Papich, 1990).

### Decongestants

Decongestants can be largely divided into sympathomimetic amines such as pseudoephedrine, ephedrine, phenylephrine, phenylpropanolamine and imidazolines such as oxymetazoline, xylometazoline and tetrahydrozoline. Sympathomimetic amines and imidazolines are used as decongestants because of their vasoconstriction effects.

Among these, pseudoephedrine is the most common decongestant associated with toxicosis in small animals, more commonly dogs than cats (Papich, 1990). Pseudoephedrine has been commonly used in cold and allergy preparations, but due to its illicit use in the manufacture of methamphetamine, many U.S. states now regulate its sale. Pseudoephedrine is a stereoisomer of the plant alkaloid ephedrine. Ephedrine is found in *Ephedra* spp. and *Sida cordifolia*. *Ephedra* sp. is used to produce ma huang, an herbal drug used in asthma, allergy and cold formulations, diet pills and in various supplements (Means, 1999, 2005; Ooms and Khan, 2001). Phenylephrine is found in nasal sprays and hemorrhoid creams.

Phenylpropanolamine (PPA) was commonly used in diet pills, cold and allergy products, both as OTC and prescription drugs for humans, and to treat urinary incontinence in dogs (Papich, 1990; Means, 2005). FDA issued a public health advisory in November 2000 due to increased risk of hemorrhagic stroke associated with the use of PPA in humans (Cantu, 2003). Following the advisory, it was voluntarily withdrawn from the market for human use in the United States. Although cardiotoxic effects have been reported in dogs by accidental ingestion (Crandell and Ware, 2005), PPA is still available as a veterinary prescription drug for the control of urinary incontinence in dogs.

Imidazolines are commonly used in over-the-counter eye drops and nasal sprays. Oxymetazoline is found in nasal sprays as a topical decongestant as well as treatment for allergic rhinitis, epistaxis and eye drops (marketed as Visine LR®).

Sympathomimetic amines can interact with digoxin, MAO inhibitors, halothane and methylxanthines (Means, 1999, 2005; Ooms and Khan, 2001). Certain conditions are known to predispose animals to adverse reactions when given sympathomimetic amines. These include diabetes, hypothyroidism, hyperthyroidism, cardiac disease, hypertension, seizure disorders, renal disease and glaucoma.

### Toxicity

Pseudoephedrine is used to improve urethral sphincter tone as a treatment for urinary incontinence in dogs, and is given at a dose of 1 to 2mg every 12 hours (Means, 2005). Clinical toxicosis has been reported in dogs given 5 to 6mg/kg, and death was documented in dogs given 10 to 12mg/kg (Means, 1999, 2005; Ooms and Khan, 2001).

The therapeutic dose of phenylpropanolamine for urinary incontinence in dogs is 1.1mg/kg (Crandell and Ware, 2005; Means, 2005). Elevated blood pressure was seen in beagles given 3.1mg/kg PO every 8 hours, and myocardial damage was noted in a dog given 48mg/kg.

Drugs containing ephedrine, in the form of ma huang, are often combined with caffeine, in the form of guarana, and this combination of drugs acts synergistically, enhancing the toxicity of this product. Doses of 1.3 to 88.9mg/kg ma huang given concurrently with 4.4 to 296.2mg/kg guarana have been associated with clinical toxicosis in dogs. One dog given a dose of 5.8mg/kg ma huang and 19.1mg/kg guarana died. There seems to be great individual difference in sensitivity to this combination of drugs, and prognosis is also dependent on the time that elapses between exposure and treatment (Ooms and Khan, 2001).

### Pharmacokinetics

Decongestants are rapidly absorbed by the gastrointestinal tract (Papich, 1990; Means, 2005). Ephedrine is absorbed within 2 hours of ingestion (Ooms and Khan, 2001). The onset of action is usually within 30 minutes, though it is delayed up to 8 hours with extended release products. Sympathomimetic amines are believed to cross the blood-brain barrier and the placenta, and are known to be secreted into milk. Metabolism occurs primarily in the liver. Most of a dose of ephedrine is excreted unchanged in the urine, and other decongestants are excreted 55 to 75% as the parent compound. The elimination half-life of pseudoephedrine is 2 to 21 hours and that for phenylpropanolamine is 2 to 4 hours. Urinary excretion is accelerated with low urine pH (Ooms and Khan, 2001; Means, 2005).

### Mechanism of action

Adrenergic stimulation is responsible for the effects produced by decongestants (Papich, 1990; Means, 1999, 2005; Ooms and Khan, 2001; Crandell and Ware, 2005). Stimulation of  $\alpha$ -1 receptors causes vasoconstriction and subsequent drying of the mucous membranes of the nasal mucosa and sinuses. Ophthalmic solutions decrease eye redness by constriction of conjunctival and scleral vasculature. Peripheral vasoconstriction leads to increased systemic vascular resistance and hypertension.  $\alpha$ -1 receptor stimulation can cause vasospasm of the coronary artery and myocardial necrosis. Other  $\alpha$ -adrenergic effects may include appetite suppression, CNS stimulation and mydriasis. The effects of phenylephrine and oxymetazoline are  $\alpha$ -receptor specific. Stimulation of  $\alpha$ -receptors by phenylpropanolamine causes release of endogenous catecholamines in the brain and heart, and can inhibit MAO at high doses. Stimulation of  $\beta$ -receptors is the cause of some of the cardiac effects attributed to decongestants, which include increased contractility and output, increased heart rate and tachyarrhythmia. Reflex bradycardia is possible. Bronchodilation is also mediated through  $\beta$ -receptors.

### Clinical signs

CNS stimulation is the common presentation for animals with decongestant overdose. Hyperactivity, restlessness, agitation, pacing and vocalization are seen (Papich, 1990; Means, 1999, 2005). Hallucinatory behaviors in dogs include staring into a corner or at unseen objects, perhaps even biting at them. Tremors, seizures and head-bobbing are observed. Hyperthermia can be secondary to increased activity, and DIC or rhabdomyolysis with associated renal failure are possible outcomes. Cardiovascular changes include tachycardia, reflex bradycardia and hypertension. Hypertension was described in beagles 30 to 60 minutes after dosing. Blood pressure in some dogs remained elevated for 6 hours. Animals can die from cardiovascular collapse. Vomiting, diarrhea, dehydration and anorexia were reported in a dog with phenylpropanolamine toxicosis. This dog was also ataxic, lethargic, tachycardiac and tachypneic. Eyes were bilaterally dilated with vertical nystagmus and loss of pupillary light reflex. This dog was not hypertensive, but it did not present to the veterinarian until 12 hours after ingestion (Crandell and Ware, 2005).

Ooms and Khan (2001) studied dogs accidentally overdosed with combination of ma huang and guarana herbal preparations and found that the onset of clinical signs could be as early as 30 minutes after ingestion, but was usually within 8 hours. Duration of signs ranged from 10 to 48 hours. Vomiting was seen in 47% of dogs, 5% were anorexic, 30% were tachycardic, 6% were tachypneic, 21% had mydriasis, 27% had tremors, 6% had

behavioral changes such as snapping, pacing and head shaking, 6% had seizures, 5% had depression, 5% had weakness and 5% were apprehensive. Hyperthermia was reported in 28% of these dogs.

### *Clinical chemistry*

Hypokalemia, hyperglycemia and hyperinsulinemia are usually reported in dogs with decongestant toxicosis (Means, 1999, 2005). Changes reported in a dog that had ingested phenylpropanolamine included hypoglycemia, mild hyperbilirubemia, and elevated ALT, ALP, BUN, creatinine, and CK. Blood pH and calcium levels were elevated. Polycythemia and thrombocytopenia were noted. A urine sample contained blood, hemoglobin or myoglobin, and protein. Elevated serum troponin indicates myocardial damage (Crandell and Ware, 2005).

### *Diagnosis and management*

Diagnosis of decongestant toxicosis is usually based on history and clinical signs. Some laboratories are able to test for pseudoephedrine, ephedrine and phenylpropanolamine in plasma or urine to confirm exposure, but it takes hours or days for results to be available, thus treatment must be initiated in the poisoning case before analytical results become available.

Treatment consists of detoxification, symptomatic and supportive care. Emetics use is risky due to the potential for aspiration. Gastric lavage can be performed in the stabilized, anesthetized and intubated patient after a large ingestion. Activated charcoal and cathartic should be given. Blood pressure, ECG and body temperature should be monitored closely. CBC, serum chemistry and acid-base status should be monitored every one to three days.

Tachycardia is treated with  $\beta$ -blockers. Propranolol can be administered at a dose of 0.02 to 0.06 mg/kg slowly by IV (Means, 1999, 2005; Ooms and Khan, 2001). Propranolol therapy helps to stabilize hypokalemia. Alternately, lidocaine has been used at a dose of 2 mg/kg IV by intermittent bolus or by continuous infusion at a rate of 80  $\mu$ g/kg per minute (Crandell and Ware, 2005). Crandell and Ware (2005) recommended atenolol at 0.2 mg/kg every 12 hours and enalapril 0.5 mg/kg every 12 hours, both given orally, to support myocardial function for phenylpropanolamine toxicosis. Papich (1990) recommended atropine at a dose of 0.04 mg/kg subcutaneously (SC) or IV. High peripheral vascular resistance and hypertension are relieved with  $\alpha$ -adrenergic receptor blocking agents. Prazosin can be given at 1 to 2 mg every 8 hours or phentolamine can be given at 0.1 mg/kg IV as needed (Papich, 1990; Ooms and Khan, 2001).

Severe CNS stimulation sometimes requires treatment with more than one anticonvulsant. Though acepromazine and chlorpromazine have historically been

believed to decrease the seizure threshold, they can be used to treat pseudoephedrine or ephedrine toxicosis, which induce seizures by a different mechanism. Acepromazine is given at a dose of 0.05 to 1.0 mg/kg IM, IV or SC, starting with a low dose and adding more as needed. Alternately, chlorpromazine is given IM or IV at a dose of 0.5 to 1.0 mg/kg, starting with a low dose and increasing as needed. If needed, phenobarbital can be given for refractory seizures at a starting dose of 3 mg/kg to effect (Means, 1999, 2005). Isoflurane anesthesia can be used for severe clinical signs (Ooms and Khan, 2001). Use of diazepam or other benzodiazepines is considered contraindicated because the dissociative effects of this drug class can exacerbate clinical signs of sympathomimetic amines.

Fluid therapy and cautious urinary acidification can help promote excretion (Ooms and Khan, 2001; Means, 2005). Urinary acidifiers enhance excretion of pseudoephedrine in humans and may be used in dogs. Acid-base status must be monitored closely when acidifiers are used. The dose for ascorbic acid is 20 to 30 mg/kg IM or IV every 8 hours. Ammonium chloride is given 50 mg/kg PO every 6 hours. Glucose is added to intravenous fluids to treat hypoglycemia. Overhydration must be avoided to prevent pulmonary edema in the hypertensive patient.

Adverse clinical signs associated with decongestants can last for 72 hours or more (Means, 2005). One dog with severe clinical signs after phenylpropanolamine ingestion recovered after six days of hospitalization (Crandell and Ware, 2005). Most animals respond to treatment more rapidly. Clinical signs that have been associated with an unfavorable outcome include uncontrollable seizures, DIC, myoglobinuria and head-bobbing. Ooms and Khan (2001) report that 26 out of 34 dogs recovered, usually within 10 to 48 hours, with treatment after ingestion of a ma huang and guarana combination drug. The remaining eight dogs died or were euthanized.

### **Antihistamines**

Antihistamines act by competitive inhibition of histamine at histamine receptors. Compounds referred to as antihistamines in this section are the  $H_1$  histamine receptor antagonists.  $H_2$  histamine receptor antagonists are also sold over the counter and are covered later, with drugs affecting the gastrointestinal system. They will be referred to as  $H_2$  histamine receptor antagonists (or  $H_2$ -blockers).

Many antihistamines, including brompheniramine, chlorpheniramine, clemastine, diphenhydramine, loratadine and triprolidine, are found in allergy, cold and flu formulations. Others, such as dimenhydrinate and meclizine, are used as antiemetics to treat motion sickness. Doxylamine

is used as a sedative in sleep aids. Hydroxyzine is used by veterinarians to treat canine atopy (Tegzes *et al.*, 2002).

### Toxicity

An incomplete list of antihistamines is provided in Table 28.3. Chlorpheniramine is the antihistamine most commonly associated with adverse effects in dogs (Papich, 1990; Gwaltney-Brant, 2004). The oral LD<sub>50</sub> for clemastine in dogs is 175 mg/kg. The therapeutic dose for hydroxyzine is 2.2 mg/kg, and 111 mg/kg is reported as toxic in dogs (Tegzes *et al.*, 2002). Terfenadine, which is no longer sold in the U.S., caused clinical signs of toxicosis in a dog at a dose of 6.6 mg/kg, but there is considerable individual difference in sensitivity to this drug (Otto and Greentree, 1994; Gwaltney-Brant, 2004). Electroencephalogram changes were noted in dogs dosed with 30 mg/kg, clinical signs were noted in dogs given in 100 mg terfenadine/kg per day for 2 to 3 weeks,

and vomiting was a consistent finding in dogs dosed with 150 mg/kg.

### Pharmacokinetics

Antihistamines are well absorbed by the monogastric gastrointestinal tract, but oral doses are poorly absorbed in ruminants (Adams, 2001; Gwaltney-Brant, 2004). The anticholinergic effects of antihistamines can slow absorption by delaying gastric emptying. Peak plasma concentrations usually occur within 2 to 4 hours of ingestion and the onset of clinical effects tends to be 20 to 45 minutes after ingestion. Therapeutic effects usually last from 3 to 12 hours. Antihistamines are highly protein bound. First generation antihistamines are able to freely cross the blood–brain barrier and are more likely to cause CNS effects than second generation products, which do not normally enter the CNS. Second generation antihistamines cross the blood–brain barrier if given at very high doses. Terfenadine has been detected in cerebrospinal fluid in overdose situations (Otto and Greentree, 1994).

Metabolism of antihistamines takes place predominantly in the liver. Hydroxyzine is metabolized to the active product cetirizine, which does not cross the blood–brain barrier. The elimination half-life of antihistamines is dependent on the individual compound. Most metabolites are excreted in the urine, though there is some biliary excretion of terfenadine. Antihistamines excreted into the bile can undergo enterohepatic cycling.

### Mechanism of action

Antihistamines act by competitive inhibition of histamine at H<sub>1</sub> receptors (Papich, 1990; Gwaltney-Brant, 2004). Binding is reversible, but can become irreversible or slow to dissociate at high doses, as with terfenadine (Otto and Greentree, 1994; Gwaltney-Brant, 2004). H<sub>1</sub> receptors are found in a variety of tissues including: mast cells of the skin; smooth muscle of airways, gastrointestinal tract, urogenital tract and cardiovascular system; endothelial cells and lymphocytes; and mammalian CNS. Histamine produces dermal itching and allergic responses in the skin and contraction of smooth muscle in the bronchial tree and intestine. Low doses of histamine produce a rapid onset of vascular dilation. The wheal-and-flair reaction associated with histamine release is due to increased vascular permeability. Histamine in the CNS modulates sleep/wake cycles.

Antihistamines are used to block allergic response and reduce itching. Antihistamines block smooth muscle contraction, reducing bronchoconstriction and affecting vascular and uterine smooth muscle. Effects on intestinal smooth muscle can cause gastrointestinal disturbances. Antihistamines also prevent increases in vascular permeability associated with histamine release. CNS effects produced by antihistamines can include sedation or excitement.

Muscarinic stimulation is believed to be involved in motion sickness-induced vomiting. The antimuscarinic actions of antihistamines decrease nausea and vomiting (Papich, 1990). Gastrointestinal motility is decreased, and respiratory suppression is sometimes seen with antihistamines. Phenothiazine-type antihistamines also block  $\alpha$ -adrenergic receptors. Allergic reactions to antihistamines have been noted.

### Clinical signs

Clinical signs of antihistamine overdose are usually evident within half an hour of dosing. Signs of CNS depression often occur with therapeutic doses of first-generation antihistamines and include sedation, ataxia and drowsiness. More severe clinical signs such as profound depression, coma and respiratory suppression incompatible with life can occur. A dog with hydroxyzine toxicosis presented with tachycardia and weakness progressing to stupor, coma, loss of gag reflex and apnea (Tegzes *et al.*, 2002). Higher doses of antihistamines can have a stimulatory effect on the CNS, particularly in children and young animals. These effects are less common in adults. Overdosed individuals appear to experience hallucinations, lack of coordination, disorientation, irritability, anxiety, aggression, seizures and pyrexia.

Vomiting and diarrhea have been associated with first-generation antihistamines. Anticholinergic effects include dry mucous membranes, fixed and dilated pupils, tachycardia and arrhythmia, and animals can be either hypertensive or hypotensive. Cardiac abnormalities were documented in humans and dogs that ingested terfenadine (Otto and Greentree, 1994; Gwaltney-Brant, 2004). Animals can have allergic reactions to topical or oral antihistamines. A list of associated clinical signs includes dermatitis, pyrexia and photosensitization (Gwaltney-Brant, 2004). Teratogenic effects have been detected in experimental animals treated with piperazine.

Metabolic acidosis and electrolyte abnormalities have been documented based on serum chemistry of antihistamine overdosed animals, but overall changes are non-specific. Changes reported on postmortem examination also tend to be nonspecific. Rhabdomyolysis and associated renal lesions or DIC are possible complications of antihistamine toxicosis.

### Management

Diagnosis of antihistamine toxicosis is usually based on history and clinical signs. Laboratory testing of urine or plasma can be helpful to confirm exposure, but results will be delayed for hours or days and quantitation is unlikely to be of value.

Emetics are appropriate to promote gastric emptying in asymptomatic animals that recently ingested large doses of antihistamines, but caution is advised because

onset of clinical signs is sometimes rapid. Gastric lavage of the anesthetized, intubated animal is more appropriate in the treatment of symptomatic animals. Activated charcoal and a cathartic are instilled after lavage or given to the stable patient. Multiple doses of activated charcoal are needed to interrupt enterohepatic cycling.

Drugs such as penicillin G and NSAIDs have been recommended to reduce protein binding and enhance excretion (Tegzes *et al.*, 2002). However, this may worsen clinical signs in the short term by making the antihistamine more bioavailable.

Serum chemistry should be assessed and monitored for hydration, electrolyte balance, acid-base status, and liver and kidney function. Animals with poor hepatic or renal function can have a decreased rate of antihistamine elimination (Gwaltney-Brant, 2004). Cardiac function, blood pressure and body temperature should be monitored as well. Respiratory function should be closely monitored and intubation is sometimes required to support the comatose patient.

Fluid therapy is useful to maintain hydration and for cardiac support and diuresis. Imbalances in electrolytes and pH need to be corrected. Animals rarely require treatment for hypotension or mild to moderate cardiac arrhythmias, which will usually respond to fluid therapy. Epinephrine should not be used to treat promethazine overdose (Staley and Staley, 1995). Promethazine inhibits adrenergic receptors and addition of epinephrine can lead to further decrease in blood pressure. Atropine should not be used, as it can potentiate the anticholinergic effects of antihistamines.

Seizures can be treated cautiously with benzodiazepines or short-acting barbiturates. The depressive effects of antihistamines will be additive with the effects of sedatives, causing "rebound depression." Though cholinergic signs are sometimes present, treatment with physostigmine is contraindicated as it potentiates cardiovascular dysfunction and seizures.

Animals overdosed with antihistamines usually improve within 24 hours, though signs sometimes persist for up to three days. Prognosis is dependent on the severity of signs and is guarded in animals presenting with seizures or coma (Gwaltney-Brant, 2004). Tegzes *et al.* (2002) report recovery of a comatose dog that had been overdosed with hydroxyzine, though the authors note that a week or two of supportive care could be required in such cases.

## DRUGS USED TO TREAT GASTROINTESTINAL SYMPTOMS

This classification includes antacids, laxatives and anti-diarrheal drugs.

## Antacids

H<sub>2</sub> histamine receptor antagonists and mineral antacids are used to increase gastric pH and associated discomfort. Use of these products to aide in healing of gastroduodenal ulcers secondary to NSAID use is noted in a previous section. Few adverse effects have been reported with these drugs.

### H<sub>2</sub> histamine receptor antagonists

H<sub>2</sub> histamine receptor antagonists include cimetidine, famotidine, nizatidine and ranitidine. Cimetidine impairs gastrointestinal absorption of some drugs and prolongs the effects of others by inhibiting their metabolism by microsomal enzymes.

#### Pharmacokinetics

Cimetidine is rapidly absorbed and 70% of a given dose is bioavailable. Absorption can be slowed by the presence of food in the stomach. The mean absorption time for ranitidine was approximately an hour and absorption was not impaired by the presence of food in the stomach. Ranitidine is 73% bioavailable in dogs and 27% available in horses after oral dosing. Famotidine is poorly absorbed and only 37% bioavailable. Nizatidine is rapidly and almost completely absorbed (Boothe, 2001). H<sub>2</sub> receptor antagonists (or H<sub>2</sub>-blockers) are less lipid soluble than H<sub>1</sub> receptor antagonists (or H<sub>1</sub>-blockers) and are less likely to cross the blood-brain barrier. Ranitidine is about 15% protein bound.

Cimetidine and ranitidine are metabolized predominantly in the liver. Seventy-three percent of an oral dose of ranitidine undergoes hepatic metabolism in people, compared to 40% in dogs. Unchanged cimetidine, famotidine and nizatidine are excreted in the urine. The plasma half-life for cimetidine is about an hour, but can be prolonged in individuals with renal or hepatic insufficiency. The elimination half-life of ranitidine is 2.5 hours in humans and 4 hours in beagles (Boothe, 2001).

#### Mechanism of action

H<sub>2</sub> receptor antagonists specifically bind to and block the actions of H<sub>2</sub> receptors by competitive inhibition. H<sub>2</sub> receptors are present in the enterochromaffin cells of the gastric mucosa and histamine stimulates acid secretion and, to a limited extent, pepsin secretion (Adams, 2001; Tegzes *et al.*, 2002). High doses of histamine produce a slow onset, prolonged vasodilatory response. H<sub>2</sub> receptor inhibitors decrease acid and pepsin secretion. They also block some of the cardiovascular effects of histamine (Adams, 2001). Famotidine is nine times more potent as a H<sub>2</sub>-blocker than ranitidine, which is five to 12 times more potent than cimetidine. Famotidine also has the longest duration of clinical effects (Boothe, 2001).

Cimetidine reduces hepatic blood flow by around 20% and inhibits microsomal cytochrome P450 enzymes, thus it interferes with metabolism of other drugs.

#### Clinical signs

Minor side effects can be expected to occur in animals.

### Mineral antacids

A list of common active ingredients in mineral antacids can be found in Table 28.4. Products may contain more than one active ingredient. Sodium bicarbonate is present in baking soda and in effervescent antacid products. These products are common in many households, and may be accidentally ingested by pets or administered by pet owners. They are used in veterinary medicine to decrease gastric hyperacidity and treat peptic ulcers, uremic ulcers, reflux esophagitis and rumen acidosis secondary to grain overload (Boothe, 2001). Few adverse effects are associated with mineral antacids (Papich, 1990).

Sodium bicarbonate and calcium carbonate are absorbed after ingestion. Transcutaneous absorption of sodium bicarbonate across damaged skin can occur (Gonzalez and Hogg, 1981). Some of the magnesium in magnesium salt-containing antacids is absorbed, and hypermagnesemia has been reported with repeated dosing (Boothe, 2001).

Mineral antacids increase gastric pH. Rebound acid secretion may occur when dosing is discontinued. Some mineral antacids inactivate pepsin and some bind bile salts (Boothe, 2001). Magnesium-containing salts have a laxative effect, and aluminum-containing salts have a constipating effect, thus these active ingredients are often used in combination. Aluminum complexes phosphate in the intestine and aluminum hydroxide has been used to decrease phosphate absorption in patients with renal disease (Segev *et al.*, 2008).

Carbon dioxide is produced rapidly when sodium bicarbonate is introduced to an acid, and this reaction may cause gastric distension (Boothe, 2001). Chronic use of calcium carbonate antacids may produce metabolic

acidosis, hypercalcemia, hypophosphatemia and calciuria with urolithiasis and metastatic calcification (Fitzgibbons and Snoey, 1999; Boothe, 2001).

Laxatives, cathartics and enemas

Drugs in this category are designated as bulk-forming laxatives, lubricant laxatives, irritant laxatives, hyperosmotic cathartics or enemas.

Bulk-forming laxatives

Nonabsorbable polysaccharide cellulose derivatives are used as bulk-forming laxatives. Natural sources include psyllium or plantago seed, wheat bran and fruits such as prunes. Synthetic forms include methylcellulose and carboxymethylcellulose. These products act by absorbing water in the gastrointestinal tract and swelling the softened fecal mass, resulting in intestinal distension and reflex peristaltic contractions. Intestinal bacteria act on cellulose and hemicellulose and produce volatile fatty acids, enhancing the osmotic effect. Fluid feces and tympany can result (Boothe, 2001). No serious adverse effects have been reported in companion animals, though these products cause fluid and electrolyte loss secondary to diarrhea. Papich (1990) suggests that subsequent dehydration can lead to intestinal impaction. Animals treated with bulk-forming laxatives should have fresh water available. If diarrhea occurs, monitor hydration and electrolyte status and correct as needed.

Lubricant laxatives

Lubricant laxatives, including mineral oil and white petrolatum, are hydrocarbon mixtures derived from petroleum. Mineral oil is frequently used in large animals and white petrolatum products are used to treat trichobezoars in cats (Papich, 1990). These large hydrocarbons are minimally absorbed and act by coating feces with a film that entraps moisture and lubricates passage. Hydrocarbon laxatives reduce absorption of fat soluble vitamins and possibly other nutrients, thus chronic use can produce deficiencies. The small amount of absorbed hydrocarbons can provide a nidus for granuloma formation in the intestinal mucosa, mesenteric lymph nodes or liver. Adverse effects, however, are rarely reported with lubricant laxatives.

Irritant laxatives

Table 28.5 lists common types of irritant laxative. Phenolphthalein laxatives are often chocolate flavored, increasing palatability, but are only effective in primates and swine (Boothe, 2001). Bisacodyl is similar to phenolphthalein. Vegetable oil products contain irritant fatty

acids such as ricinoleic acid in castor oil, linoleates in linseed oil and oliveates in olive oil. Common anthraquinone-type cathartics are derived from plants: cascara sagrada from *Rhamnus* spp., senna from *Senna* spp. and aloin from *Aloe* spp. Danthron (1,8-dihydroxyanthroquinone) is synthetic, but is considered the prototype for the anthraquinone laxative group.

Five percent of an oral dose of bisacodyl is absorbed. There is some absorption of anthraquinone glycosides, and delayed transit through the small intestine decreases effectiveness. Anthraquinones are secreted in the milk, causing clinical effects in the nursing young (Boothe, 2001).

As suggested by the term irritant laxative, these compounds cause contact irritation of gastrointestinal mucosa and increase fluid secretion into the lumen. Diarrhea occurs 6 to 8 hours after diphenylmethane cathartics are administered and can be severe if large doses are given (Boothe, 2001). Pink discoloration of alkaline urine is seen with phenolphthalein. Acidic urine will turn pink with addition of sodium hydroxide or sodium bicarbonate (Papich, 1990).

Vegetable oil laxatives are hydrolyzed by lipase in the small intestine and form sodium and potassium salts which act as soaps, producing irritation (Boothe, 2001). Ricinoleic acid is the most potent of these compounds, and initiates rapid and complete colonic emptying. This clinical effect is seen 4 to 8 hours after administration of castor oil in small animals, and 12 to 18 hours post-dosing in large animals. Animals treated with castor oil should be fed moist, bulky material afterward.

Anthraquinones are hydrolyzed by bacteria in the large intestine to emodins which stimulate the myenteric plexus. Anthraquinones produce catharsis after 6 to 12 hours in small animals and 12 to 36 hours in large animals (Boothe, 2001). Catharsis is accompanied by reduced hydration and electrolyte loss. Abdominal pain or colic is produced by large doses. Changes in urine color are reported with anthraquinones. With chronic use of these laxatives, the myenteric plexus will degenerate causing a loss in intestinal motility. Animals treated with irritant cathartics should be monitored for hydration and electrolyte status with correction as needed.

Some irritant cathartics increase prostaglandin synthesis, and NSAIDs minimize this effect.

### *Hyperosmotic cathartics*

Magnesium sulfate, or Epsom salt, is a common osmotic cathartic and is used in 6% isotonic solution. Other magnesium-containing cathartics include magnesium hydroxide (milk of magnesia), magnesium oxide and magnesium citrate. Sodium sulfate (Glauber's salt), sodium phosphate, potassium sodium tartrate and sodium tartrate (Rochelle salt) are used as cathartics and ingestion of large quantities of sodium chloride produces catharsis. The sugar alcohols mannitol and sorbitol, and synthetic disaccharides such as lactulose, are also used as cathartics. Polyethylene glycol 3350 (PEG) once available only with prescription for whole-bowel irrigation before colonoscopy procedures and to treat body-packer patients (Farmer *et al.*, 2003) is currently available over the counter (MiraLAX®).

Osmotic cathartic use should be avoided in dehydrated animals, and water should be freely available. Other contraindications for use include congestive heart failure, gastrointestinal stasis and hepatic or renal impairment (Henninger and Horst, 1997; Ezri *et al.*, 2006). Hyperosmotic cathartics draw water into the intestinal tract via osmosis. Intestinal distension promotes motility. Effects are usually evident 3 to 12 hours after dosing in monogastrics and within 18 hours in ruminants.

There is minimal slow absorption of most cathartics, but up to 20% of the magnesium in a dose of magnesium sulfate is absorbed in the small intestine (Henninger and Horst, 1997; Boothe, 2001). Renal failure enhances systemic magnesium accumulation, leading eventually to hypermagnesemia. Administration of magnesium sulfate with dioctyl sodium sulfosuccinate in horses increases magnesium absorption due to mucosal damage (Henninger and Horst, 1997). Magnesium ions promote the release of cholecystokinin which promotes peristalsis. Systemic effects of magnesium include inhibition of calcium ion release at neuromuscular junctions, inhibition of acetylcholine release, decreased sensitivity of motor endplates and decreased excitability of myocyte membranes, leading to paralysis. Clinical signs of hypermagnesemia secondary to magnesium sulfate administration in the horse occurred within 6 hours of administration and included perspiration, progressive tremors, recumbence, severe tachycardia, tachypnea, pale mucous membranes, prolonged capillary refill times, flaccid paralysis of the head and neck, and loss of flexor and perineal reflexes. Horses remained alert.

Absorbed phosphate from phosphate containing cathartics can deplete intracellular potassium ions and induce hypokalemia. Lactulose reaches the colon largely intact and is degraded into lactic acid and acetic acid by

large intestinal microflora. Gas is generated and can cause tympany. The associated decrease in pH has been used for ion trapping of ammonium to prevent hepatic encephalopathy in animals with liver failure (Boothe, 2001).

Dehydration and electrolyte imbalances are the most common changes associated with cathartics (Papich, 1990). Management is aimed at correcting these imbalances. Calcium is used to treat hypermagnesemia. Calcium ions displace magnesium ions from cell membranes. Response to therapy is rapid, but repeated dosing with calcium gluconate is sometimes needed. Diuresis with IV fluids and furosemide promote renal excretion. Henninger and Horst (1997) reported that horses treated for hypermagnesemia had serum magnesium concentrations within reference ranges the next day. Electrolyte changes in asymptomatic patients given oral sodium phosphate for pre-surgical catharsis returned to normal within 24 hours (Ezri *et al.*, 2006).

### *Enemas*

An enema is a material given intrarectally to induce defecation. Commonly used enemas include soft anionic soap in water, isotonic or hypertonic sodium chloride, sorbitol, glycerol, sodium lauryl sulfate, sulfoacetate, mineral oil, olive oil and phosphate salts (Boothe, 2001).

Toxicosis has been reported in people and small animals administered hypertonic sodium phosphate solutions, or fleet enemas. Debilitated cats are commonly affected (Papich, 1990). Predisposing factors include administration of a full-strength fleet enema (intended for human use) to a small animal, dehydration, preexisting electrolyte abnormalities, renal or hepatic dysfunction, colonic dilatation and colonic ulceration. A 60 mL hypertonic phosphate enema can cause toxicosis in a cat (Roder, 2004b).

Sodium and phosphate are absorbed in the colon, and absorption is increased with disruption of the mucosa or in animals with chronic constipation (Jorgensen *et al.*, 1985). Uptake of phosphate promotes cellular uptake of calcium, and phosphate can directly bind serum calcium, both contributing to hypocalcemia. Adverse effects associated with sodium phosphate enemas usually occur within an hour of dosing. Vomiting and bloody diarrhea have been observed. Nervous signs that have been reported include depression, ataxia, anxiety, neuromuscular irritability and convulsions. Dehydration, weak pulses, tachycardia, hypothermia, shock and death have also been observed. Serum chemistry in these patients often reveals hyperphosphatemia, hypernatremia, hypocalcemia, metabolic acidosis and hyperglycemia. Hyperkalemia or hypokalemia can occur.

Intensive fluid therapy is required in acute sodium phosphate enema overdose situations. The purpose is to correct dehydration, electrolyte imbalances, acid-base

imbalances, hypoglycemia and treat circulatory shock. Isotonic saline solution can increase renal calcium loss and thus should be avoided. Saline solutions containing 0.45% sodium chloride and 2.5% dextrose, or 2.5 to 5.0% dextrose solutions, have been recommended for hypoglycemic patients. Lactated Ringers solution can be used in hyperglycemic patients. Fluid therapy may be needed for four days. Jorgensen *et al.* (1985) suggested instillation of aluminum carbonate or aluminum hydroxide to bind phosphate in the intestine and maintain body temperature. Prophylactic antibiotics are given for compromise of the colonic mucosa. Intoxicated cats showed improvement within 6 h of initiation of therapy, and electrolyte imbalances resolved within two days.

### Antidiarrheal drugs

Active ingredients in products used to treat diarrhea include bismuth subsalicylate, kaolin-pectin and opioid receptor agonists. Most of the toxic effects associated with bismuth subsalicylate are due to the salicylate component; therefore this formulation is discussed in more detail with aspirin and salicylates. Bismuth is believed to adsorb bacterial endotoxin and have a direct antimicrobial effect.

Kaolin and pectin were previously the active ingredients in the popular over-the-counter product Kaopectate, but bismuth subsalicylate is now used. Kaolin is hydrated aluminum silicate and acts as an adsorbent. Pectin is a carbohydrate extracted from citrus fruit that acts as an adsorbed and intestinal protectant. Toxicosis attributed to kaolin-pectin preparations has not been observed, though these products are likely to decrease absorption of other drugs.

The over-the-counter drug Imodium® and the prescription drug Lomotil® contain the opioid receptor agonists loperamide and diphenoxylate, respectively. Loperamide is sold in 2mg capsules and liquids at a concentration of 0.20mg/mL. The effective dose for loperamide is 0.08mL/kg PO every 12 hours in small dogs and cats. These products are poorly absorbed. They function to decrease gastrointestinal secretion and motility. Side effects include constipation, abdominal pain, vomiting and drowsiness. Collies and other dog breeds with a mutation in the *ABCB1* gene (formerly *MDR1*) are believed to have increased susceptibility to loperamide (Sartor *et al.*, 2004). Clinical signs in collies include salivation, weakness, ataxia and disorientation. Management consists of monitoring and supportive and symptomatic care. Activated charcoal can be given to decrease intestinal absorption in the case of a large ingestion. Neuromuscular signs in one collie resolved about a day after the drug was discontinued (Sartor *et al.*, 2004). The opioid antagonist naloxone is used to manage severe clinical signs, but is usually

unnecessary. Naloxone has a short half-life, requiring repeated dosing as needed (Papich, 1990).

### TOPICAL DRUGS

Toxicosis secondary to topical preparations can occur through dermal absorption or ingestion. Cats in particular are fastidious groomers and any product that is used on a cat is likely to end up in the cat. Some animals, dogs in particular, will chew through a tube containing a topical drug (Papich, 1990).

Like other OTC drugs, topical products frequently contain more than one active ingredient. Antibiotic preparations can contain bacitracin, neomycin and polymyxin. Though rare, topical hypersensitivities have been reported, these antimicrobials are poorly absorbed from the normal gastrointestinal tract, limiting their systemic effects (Papich, 1990). However, if large quantities are ingested, damage to the resident gastrointestinal microflora can lead to diarrhea and discomfort. Use of these products in hamsters or guinea pigs, which are predisposed to develop antibiotic-induced enterocolitis, should probably be avoided.

Benzoyl peroxide is present in some topical antiseptics and acne medications. It acts by releasing hydrogen peroxide, which has antibacterial and keratinolytic effects and promotes epithelial cell turnover. Hyperemia and blistering have been reported with overuse of products containing benzoyl peroxide. Ingestion can lead to intra-gastrointestinal gas production and distension. Emetics are contraindicated if this should happen. Gastric decompression requires use of a stomach tube.

### CONCLUSIONS

OTC drugs, which are widely available to consumers, encompass a large number of products, many containing multiple active ingredients, developed for oral, topical, intraocular, intranasal and intrarectal administration. Of the thousands of OTC drugs available, only a fraction were addressed in this chapter, including analgesics, cold, flu and allergy medications, and drugs used to treat gastrointestinal symptoms. Obtaining a thorough history is of great importance when dealing with suspect OTC drug-related problems. It is often helpful if the owner brings the drug container to the veterinarian as a source of information on the active ingredients, indications for use and manufacturer identification, telephone number or address. Treatment for most OTC drugs includes decontamination, stabilization and symptomatic and supportive care with careful monitoring.

# Toxicity of drugs of abuse

Karyn Bischoff

## INTRODUCTION

Potential for exposure to illegal drugs exists for many companion animals, horses and even livestock on occasion. Forty-seven percent of graduating American high-school students surveyed had used illegal drugs in some form (Latimer and Zur, 2010). The illegal drug trade in the United States peaked in the late 1970s, declined in the 1980s and early 1990s, and increased again through the late 1990s to stabilize since 2000 (Compton *et al.*, 2005).

Marijuana is one of the most prevalent recreational drugs in the world after legal substances ethanol and nicotine (Janczyk *et al.*, 2004; Compton *et al.*, 2005; Johnson *et al.*, 2005; Vitale and van de Mheen, 2005; Latimer and Zur, 2010). Cocaine is probably second in popularity among illegal substances in some areas of the United States and Europe (Kisseberth and Trammel, 1990; Dumonceaux, 1995; Queiroz-Neto *et al.*, 2002; Vitale and van de Mheen, 2005). Since the 1980s, the term “club drugs” has come into use, representing drugs frequently found at nightclubs and all-night “rave” parties. Club drugs are a continuing trend (Smith *et al.*, 2002; Banken, 2004). Many are stimulants, though depressants may be used to counter the effects of the stimulants or given secretly to sedate a victim for the purpose of theft assault. Hallucinogens are also used. Some of the most common club drugs include ketamine, 3,4-methylenedioxymethamphetamine (MDMA), commonly called “ecstasy,” flunitrazepam (Rohypnol®), the “date rape drug,” and  $\gamma$ -hydroxybutanoic acid (GHB). Beginning in late 2010, the abuse of the legal substances mephedrone and methylenedioxypyrovalerone, marketed as “bath salts,” has come into vogue, prompting an emergency order to remove them from the market in Louisiana.

## Illicit drugs and small animals

Among companion animals, dogs are the most susceptible to poisoning with illicit substances, though toxicoses occasionally arise in cats, ferrets, birds or other household pets. Exposure may be through voluntary ingestion or malicious poisoning and other forms of animal abuse (Kesseberth and Trammel, 1990). There are reports of adolescents entertaining themselves by intoxicating dogs, cats and birds with second-hand marijuana smoke (Schwartz and Riddle, 1985; Buchta, 1988).

Police dogs are at particular risk for ingestion of illegal drugs. They may come into contact with large quantities of the high-purity chemicals in the line of duty (Dumonceaux and Beasley, 1990; Kesseberth and Trammel, 1990). They may ingest whole bags of drugs which must be removed surgically or via endoscopy to prevent rupture and massive exposure. Police dogs may be at increased risk for malicious poisonings. Recently, news reports document the use of dogs as “drug mules” to move bags of heroin, which were surgically implanted. Deaths in several of these dogs were attributed to secondary infections.

Illegal drug ingestion in small animals presents a diagnostic challenge, and often an ethical challenge, to the clinician. Pet owners may not be aware of what the animal was exposed to, as in the case of animal intoxication by adolescents (Schwartz and Riddle, 1985; Buchta, 1988). Jones (1978) reported that a dog ingested illicit substances from a neighbor’s garbage can. Violence is intrinsic to the drug culture in poor neighborhoods (Johnson and Myron, 1995). It could take the form of malicious poisoning or other forms of animal abuse. Suspected malicious poisoning with illicit drugs has been reported (Bischoff *et al.*, 1998).

The pet owner who is aware that the animal ingested an illegal substance may be reluctant to admit it (Godbold *et al.*, 1979; Kisseberth and Trammel, 1990; Dumonceaux, 1995; Welshman, 1996; Frazier *et al.*, 1998; Janczyk *et al.*, 2004; Volmer, 2005). A veterinarian must balance client confidentiality with legal obligation. The client bringing the pet to a veterinary clinic is aware that it requires medical attention, but the threat of legal action can discourage them from disclosing critical information. It is prudent for the veterinarian to be aware of the local laws concerning animal abuse, drug possession and their responsibility towards reporting illegal activities. Sadly, animals have been euthanized in part due to an incomplete history (Smith, 1988). The owner must be made aware that a proper history is required if appropriate treatment is to be administered.

Diagnostic laboratories have screens available to detect the presence of many illegal drugs, but these screens take time and may be expensive (Janczyk *et al.*, 2004). New over-the-counter urine testing kits are available at pharmacies. One study has found these kits useful in detection of barbiturates, some opioids, benzodiazepines and amphetamines in canine urine, but less accurate in the detection of other opioids and marijuana (Teitler, 2009). Awareness of the animal's home situation, including the neighborhood or the presence of adolescent children in the household, may be helpful in determining the potential for exposure to illegal substances. The astute clinician might ask if there was a party in the home when the pet became ill (Kesseberth and Trammel, 1990). Pet owners who do admit that their pet ingested illegal drugs may not be fully aware of what was ingested, or know only the street name of the drug. Drug dealers may combine drugs or make substitutions and many drugs are very similar in appearance.

## Illicit drugs and large animals

Horses may be "doped" to improve athletic performance to hide soundness or temperament problems. Cocaine has been detected in urine samples from horses at athletic events (Queiroz-Neto *et al.*, 2002; Kollias-Baker *et al.*, 2003). It is expected that such drugs would be given in relatively small doses, but dose miscalculations can occur. Exposure to plants grown for illicit drug manufacture has occurred in herbivores. There are reports of lethal marijuana exposure in cattle fed the plant as hay and horses on pasture (Cardassis, 1951; Driemeier, 1997).

Anhydrous ammonia is an ingredient in illegal methamphetamine production. It is also used to instill nitrogen into the soil for fertilization and tanks are sometimes stored near animal facilities. Unscrupulous manufacturers of the drug often steal anhydrous ammonia from farm tanks and may fail to close the tank valves before

leaving the premises. The death of 64 out of 260 dairy cattle in Michigan resulted from anhydrous ammonia theft (Fitzgerald *et al.*, 2006).

## The veterinarian and the Drug Enforcement Administration (DEA)

Title 21 of the U.S. Code of Federal Regulations establishes the DEA, which classifies drugs into five categories as listed in Table 29.1. Because some veterinary drugs, such as ketamine and phenobarbital, are coveted on the illegal drug market, failure of the veterinarian to prescribe drugs appropriately has led to loss of license and risk of imprisonment (Gloyd, 1982). A veterinarian was fined and lost his license in the year 2000 for selling steroids illegally (AVMA News, October 15, 2000) and a few years later, an Internet pharmacy was fined more than \$40,000 for contracting veterinarians to write prescriptions without examining animals and for dispensing drugs not approved by the FDA (AVMA News, April 19, 2002).

## Depressants

Substances that have a depressant effect on the central nervous system (CNS) include marijuana, barbiturates, opioids and club drugs flunitrazepam (Rohypnol®), and GHB. Ketamine, a sedative-hypnotic, will be discussed with related compound phencyclidine under the category of hallucinogens. Depressants act at a variety of receptor sites within the CNS. Some receptors are named for the drugs that bind to them, including opioid receptors and cannabinoid receptors.

## Marijuana

*Cannabis sativa* has been used for over 4000 years for its psychotropic effects (Di Marzo and De Petrocellis, 2006). Recent surveys of U.S. students found that approximately 33–37% have used marijuana by the last year of high school and 11% have used it in 8th grade (Eaton *et al.*, 2010; Latimer and Zur, 2010). Common names include marijuana, hemp or Indian hemp, pot, ganja, dagga, hashish and kief (Burrows and Tyrl, 2001). The crude product, usually called marijuana in the U.S., is produced from dried chopped leaves and the female inflorescences (Kisseberth and Trammel, 1990; Frohne and Pfänder, 2004; Volmer, 2005). Sinsemilla, Spanish for "without seeds," accounts for approximately 85% of U.S. marijuana production due to the absence of seeds and the very high content of the active ingredient. Hashish is a dried and compressed resin made from the *C. sativa* often formed into balls, sheets and cakes to be used for

TABLE 29.1 DEA drug schedules

Classification	Description	Examples
Schedule I	1. High potential for abuse. 2. No accepted medical use in U.S. 3. Lack of accepted safety for use under medical supervision.	Heroin LSD Marijuana  MDMA Mescaline Psilocybin
Schedule II	1. High potential for abuse. 2. Currently accepted medical uses, may have restrictions. 3. Severe physical or psychological dependence potential with abuse.	Amphetamine Cocaine  Methamphetamine  Morphine Opium Pentobarbital Phencyclidine
Schedule III	1. Less potential for abuse than Schedule I or II drugs. 2. Currently accepted medical uses. 3. Moderate or low potential for physical or psychological dependence with abuse.	Ketamine  LSA Thiopental
Schedule IV	1. Low potential for abuse relative to Schedule III. 2. Currently accepted medical use. 3. Limited physical or psychological dependence potential with abuse.	Butorphanol Diazepam Flunitrazepam
Schedule V	1. Low potential for abuse compared to Schedule IV. 2. Currently accepted medical use. 3. Limited potential for physical or psychological dependence with abuse compared to Schedule IV.	Low-dose codeine preparations Low-dose opium preparations

smoking. Hashish oil, even more concentrated, may be mixed with tobacco or marijuana and smoked.

Cannabinoids are a variety of related compounds found in *C. sativa*. More than 60 are known, the most important being  $\Delta^9$ -tetrahydrocannabinol (THC). THC is a lipid soluble monoterpene present in all parts of the plant, with highest concentrations in the flowers and leaves (Ashton, 2001; Burrows and Tyrl, 2001). Common cultivars grown in 1974 contained approximately 1% THC, whereas the recent average THC concentration in seized marijuana samples was 10.1% (Anonymous, 2011). Hashish contains 5% THC on average, and hashish oil averages 15% THC and may be added to a marijuana cigarette to double the potency.

There are a variety of accepted and controversial medical uses for marijuana and its active compound. Some states allow possession and use of marijuana for medical treatment under certain conditions. Though laws change frequently, states that allow restricted medical use of marijuana as of February 2011 include Alaska, Arizona, California, Colorado, Hawaii, Maine, Michigan, Montana, Nevada, New Jersey, New Mexico, Oregon, Rhode Island, Vermont, Washington and the District of

Columbia. Maryland restricts court penalties for marijuana possession if medical necessity can be proven. Prescription products include dronabinol (Marinol<sup>®</sup>) capsules, which contain THC in sesame oil and are currently classified as a Schedule I drug by the DEA, and Nabilone (Cesamet<sup>®</sup>), a synthetic form of THC classified as Schedule II. These drugs are used to treat nausea in cancer patients and may be superior in efficacy to other antiemetic drugs such as metoclopramide. They improve weight gain among patients with AIDS, cancer or Alzheimer's disease, and have been considered for use in treatment of glaucoma, multiple sclerosis, chronic pain, epilepsy and various psychiatric disorders (Di Marzo and De Petrocellis, 2006). The recently developed drug 1-pentyl-3-(1-naphthoyl)indole, or JWH-018, though not structurally related to THC, has a similar action at cannabinoid receptors. JWH-018 is mixed with leafy herbs and sold as "spice" or "K2" to be smoked as an alternative to marijuana. These products are illegal in some countries and have been temporarily banned (through the year 2011) in the United States (Anonymous, 2011).

Illegal marijuana is most commonly used in the form of marijuana cigarettes called "joints" or "reefers."

Alternately, marijuana may be rolled in a tobacco leaf and called a "blunt" or smoked using a water pipe ("bong") or other type of pipe. Marijuana may be brewed into a tea, or more commonly baked into brownies, cookies or cakes (Ashton, 2001; Volmer, 2005). Many veterinary exposures come from the ingestion of tainted baked goods.

Marijuana cigarettes are sometimes dipped in a mixture of phencyclidine, methanol and formaldehyde. Ketamine, opium, cocaine and heroin may be added to a marijuana cigarette or used with marijuana. Street names for marijuana include "grass," "hemp," "Mary Jane" or "MJ," "pot," "puff" and "weed."

Dogs less than 1 year of age are the most likely companion animal to ingest marijuana (Kisseberth and Trammel, 1990; Janczyk *et al.*, 2004). Marijuana leaves or marijuana cigarettes were recovered from 203 of 213 canine ingestions. Baked goods, as noted, are attractive to dogs (Jones, 1978; Godbold *et al.*, 1979; Janczyk *et al.*, 2004). Fresh plants and refined resins are also occasionally available to companion animals. Intentional intoxication of small animals using second-hand smoke has been reported (Schwartz and Riddle, 1985; Buchta, 1988; Frohne and Pfänder, 2004).

Large animals have been exposed through grazing marijuana or ingesting dry baled marijuana as hay (Cardassis, 1951; Driemeier, 1997). Horses have been bedded on hemp fiber, which presents an impaction risk (Green, 1996; Smith and Papworth, 1996).

### Toxicity

Few veterinary deaths have been reported from marijuana intoxications. Marijuana has a very wide safety margin in that the lethal dose is approximately 1000 times the effective dose (Volmer, 2005). No deaths were reported in dogs and monkeys ingesting 3 to 9 grams marijuana per kg of body weight (Burrows and Tyrl, 2001). Janczyk *et al.* (2004) documented the survival of a dog that ingested 26.8g marijuana/kg body weight. The LD<sub>50</sub> for oral marijuana exposure in rats is 666 to 1000mg/kg (Kisseberth and Trammel, 1990; Burrows and Tyrl, 2001). Driemeier (1997) reports that four out of five debilitated cattle died after the group ingested 35kg of dried marijuana. Horses and mules have died after ingesting large quantities of fresh marijuana of the species *Cannabis indica* (Cardassis, 1951).

### Toxicokinetics

Absorption of inhaled THC approaches 50% (Burrows and Tyrl, 2001; Janczyk *et al.*, 2004). Gastrointestinal absorption is erratic in humans and dogs. Blood concentrations obtained by ingestion are 25 to 30% of those obtained by smoking in humans (Ashton, 2001). Onset of clinical signs is delayed compared to the 6 to 12 minutes

associated with the respiratory route to 30 to 60 minutes or longer after ingestion.

Circulating THC is up to 99% protein bound in humans (Volmer, 2005). Plasma concentrations peak within 2 to 3 hours. This lipid soluble compound is rapidly distributed to the brain and other tissues. Within the brain, THC accumulates in the neocortical, limbic, sensory and motor areas. Distribution is blood flow dependent and peak accumulation in adipose tissue occurs in 4 or 5 days in humans (Ashton, 2001). The plasma half-life of THC is short due to the rapid tissue distribution.

THC is rapidly metabolized by the mixed-function oxidase system of the liver (Burrows and Tyrl, 2001). The significant first-pass effect may account for the lower blood concentrations associated with ingestion versus inhalation (Ashton, 2001; Janczyk *et al.*, 2004). 11-Hydroxy- $\Delta^9$ -THC is the physiologically active major metabolite of THC (Volmer, 2005). There are more than 20 other known metabolites (Ashton, 2001).

Between 65 and 90% of a dose of THC is excreted as the parent compound or conjugated metabolites through the feces and there may be significant enterohepatic cycling (Kisseberth and Trammel, 1990; Ashton, 2001; Volmer, 2005). Ten to 25% of THC is excreted as the parent compound, metabolites and conjugates in the urine.

### Mechanism of action

CB1 and CB2 are the cannabinoid receptors that have been identified in rats, guinea pigs, dogs, monkeys, pigs and humans (Ashton, 2005). CB1 is widely distributed in certain areas of the brain: receptors in the cerebral cortex regulate cognitive function, receptors in the hippocampus and amygdala are important in emotional status, cerebellar receptors influence dopaminergic signaling, movement and postural reflexes, and receptors in the basal ganglia, brainstem and autonomic nervous system (ANS) regulate pain perception and cardiovascular and gastrointestinal function (Ashton, 2005; Di Marzo and De Petrocellis, 2006). CB1 receptors are located within lipid membranes of presynaptic neurons and coupled to G-proteins. They inhibit cAMP and stimulate mitogen-activated protein kinases to modulate control of ion channels, particularly voltage-activated calcium ion channels and potassium channels (Ashton, 2005; Di Marzo and De Petrocellis, 2006; Janczyk *et al.*, 2004). The end result is inhibition of release of neurotransmitters, both excitatory and inhibitory. CB1 receptors also activate phospholipase C and PI-3-kinase. The endogenous ligand for cannabinoid receptors, known as endocannabinoids, are derived from arachidonic acids and closely related to prostaglandins. CB2 receptors are absent in the CNS but found in the peripheral nervous system (PNS) and immune system where they play a part in inflammation and pain regulation (Di Marzo and De Petrocellis, 2005;

Volmer, 2005). CB2 receptors regulate ceramide biosynthesis (Di Marzo and De Petrocellis, 2006).

### Clinical signs

Clinical signs of marijuana intoxication in dogs are similar to those in humans (Dumonceaux and Beasley, 1990; Dumonceaux, 1995). Signs are evident 30 to 60 minutes after ingestion. The signs attributable to the CNS include depression, ataxia, mydriasis, disorientation, behavioral disturbances, hyperesthesia, recumbence, tachycardia, hypotension or less commonly, stupor, tremors or seizures. Ingestion exposures may cause mild gastrointestinal irritation and vomiting. Other signs that have been reported include hypothermia or, less commonly, hyperthermia, as well as bradycardia, vocalization and compulsive eating. Severe clinical signs described in a ferret included ataxia with rapid onset of coma, muscle twitching, hypotension and hypothermia (Smith, 1998). A case of atopic dermatitis was reported in a dog living in a home where *C. sativa* had been cultivated (Evans, 1989).

Onset of clinical signs in cattle began 20 hours after ingesting dried plant material and included muscle tremors, hypersalivation and mydriasis. Animals were reluctant to move and lacked coordination. Four of the five exposed animals died within 3 days, one recovered with no treatment. These cattle were already debilitated at the time of exposure (Driemeier, 1997). Rapid onset of clinical signs was described in eight horses and seven mules ingesting fresh plant material, including dyspnea, tremors, hypothermia, hypersalivation, sweating, recumbence and death within 30 minutes (Cardassis, 1951).

### Treatment

The prognosis for full recovery in small animals exposed to marijuana is excellent with proper treatment. Janczyk *et al.* (2004) described 213 cases with 100% survival. Rate of recovery is dependent on dose and route of exposure. Most animals exposed to second-hand smoke recover within a few hours. Dogs who ingest a small dose of plant material usually recover within 24 hours, but those ingesting large doses can have clinical signs for several days (Kisseberth and Trammel, 1990; Dumonceaux, 1995; Burrows and Tyrl, 2001; Volmer, 2005).

Treatment for THC exposure includes decontamination, supportive and symptomatic care. Mild intoxication usually requires only observation. Gastrointestinal decontamination to decrease THC absorption can be used in animals that have ingested large quantities of marijuana or more concentrated marijuana products. Emesis may be initiated in the asymptomatic patient within an hour of ingestion, but must be avoided in animals with clinical signs such as CNS depression (Dumonceaux and Beasley, 1990; Dumonceaux, 1995). Repeated dosing with activated charcoal and cathartics helps to prevent absorption and enterohepatic cycling

and thus decreases the duration of clinical signs. THC is highly lipid soluble and, in the author's experience, intravenous lipid infusion can be used to diminish clinical signs of the THC toxicosis in dogs (unpublished information).

Observation of the patient includes monitoring cardiac function, body temperature and respiration. Stuporous or comatose dogs are at risk for respiratory suppression or hypothermia and must be treated appropriately. Marked central nervous stimulation can be treated with diazepam.

Treatment of large animals was not attempted in the few cases presented in the literature. The rapid onset of clinical signs in the horses did not allow time for veterinary intervention. Basic treatment procedures in large animals parallel those used in small animals. Gastrointestinal decontamination for large ingestions can involve gastric lavage or, in cattle, rumenotomy, and intragastric or intraruminal instillation of mineral oil or activated charcoal and cathartics. Monitoring and symptomatic and supportive care should proceed as above.

Veterinary laboratories may test blood or plasma for THC using thin-layer chromatography (TLC) or gas chromatography/mass spectrometry (GC/MS). Drug testing kits are available over the counter from pharmacies, but there is a poor correlation between blood or plasma THC levels and clinical signs (Ashton, 2001; Janczyk *et al.*, 2004).

### Pathology

There is little information on lesions associated with marijuana overdose in small animals because so few have died. Pulmonary edema was noted in a cow (Driemeier, 1997). *C. indica* was identified in the stomach of the horses with edema and petechiation of the gastric wall and myocardial hemorrhage (Cardassis, 1951).

### Barbiturates

Barbiturates are derived from the non-sedative barbituric acid. They are bitter tasting white powders in the pure form and are most frequently available as a sodium salt in weakly acidic aqueous solution. Barbiturates have been used in anesthesia and sedation and seizure control, and though still commonly used by veterinarians, are becoming more uncommon in human medicine (Kisseberth and Trammel, 1990). The four classifications of barbiturates are based on the duration of their activities. The duration of ultra-short-acting barbiturates in general is approximately 20 minutes; these drugs are given IV to effect. Examples include thiamylal sodium and thiopental sodium, both Schedule III, and methohexital sodium which is Schedule IV. The duration of short-acting barbiturates is approximately 3 hours and they are given intravenously for anesthesia. Common

examples of these are pentobarbital sodium and secobarbital sodium, both Schedule II drugs. The duration of intermediate-acting barbiturates, such as butobarbital or amobarbital, both Schedule III, is 3 to 6 hours. Long-acting barbiturates can produce clinical effects for 12 hours and these drugs have use in sedation and anticonvulsant therapy. Phenobarbital, methylphenobarbital and barbitol sodium are examples of long-acting barbiturates and are Schedule IV drugs (Kisseberth and Trammel, 1990; Branson, 2001; Volmer, 2005). Barbiturates are known as downers, reds, Christmas trees and dolls on the illegal market.

Barbiturate overdose is usually iatrogenic or due to accidental ingestion of prescription or illicit drugs. A common problem in veterinary medicine is exposure to carcasses of animals that were euthanized with barbiturates. This problem has been diagnosed by the author and reported in dogs and in wildlife in the literature (Humphreys *et al.*, 1980; Branson, 2001; Volmer, 2005). According to the AVMA News in 2003, at least 34 bald eagles have died from pentobarbital poisoning. Veterinarians and animal owners are responsible for proper carcass disposal and may be liable for wildlife poisonings (Volmer, 2005).

### Toxicity

The LD<sub>50</sub> for pentobarbital in the dog is 40 to 60mg/kg by the intravenous (IV) route or 85mg/kg per os. The oral LD<sub>50</sub> for cats is 125mg/kg. The margin of safety for barbiturates is low; the therapeutic dose may be 50 to 70% of the LD<sub>50</sub> (Kisseberth and Trammel, 1990; Branson, 2001).

### Toxicokinetics

Gastrointestinal absorption of barbiturates is variable, with rapid absorption of short-acting compounds and slower absorption of long-acting barbiturates. Barbiturates are rapidly distributed throughout the body and readily cross the blood-brain barrier (Kisseberth and Trammel, 1990; Branson, 2001; Volmer, 2005). Short-acting thiobarbiturates are highly lipid soluble and enter the brain rapidly, resulting in rapid onset of CNS depression. This is followed by rapid redistribution to tissues with less perfusion, and thus rapid clinical recovery. Longer-acting barbiturates are less lipophilic, therefore they enter and leave the brain more slowly and have a more gradual onset and longer duration of action. Barbiturates cross the placenta and fetal concentrations equilibrate with those of the dam within minutes.

There is significant variation in barbiturate metabolism and excretion based on the barbituric acid derivative, the species of animal and the individual. Barbiturates are metabolized by microsomal P450 enzymes in the liver. Barbiturates interfere with metabolism of other compounds either by binding to the P450 enzymes to block

metabolism or, in chronic exposures, by inducing P450 enzymes and increasing the rate of metabolism of xenobiotics and endogenous substances, including steroids (Volmer, 2005). Some barbiturates, in particular the short-acting thiobarbiturates, undergo significant oxidation in the tissue. Phenobarbital is metabolized very rapidly in ruminants and horses, relatively rapidly in dogs, more slowly in humans, and slower still in cats (Branson, 2001).

Barbiturates are excreted as both parent compound and metabolites in the urine. Excretion of some barbiturates is dependent on urine pH and is increased five to ten times in alkaline urine through ion trapping. Ion trapping is less effective with short-acting barbiturates, which are highly metabolized, highly protein bound drugs, and have high pK<sub>a</sub>s (Kisseberth and Trammel, 1990; Volmer, 2005). Barbitol is excreted very slowly in birds (Branson, 2001).

### Mechanism of action

Barbiturates bind to the  $\gamma$ -aminobutyric acid (GABA) receptor complex and decrease the rate of GABA dissociation (Branson, 2001). These actions increase permeability of the postsynaptic membrane to chloride, causing membrane hyperpolarization and reduced excitability. GABA receptors are found in motor and sensory areas of the cerebral cortex and possibly in the thalamus, where barbiturates act to control seizures and induce anesthesia. Barbiturates also act to inhibit glutamate receptors and decrease norepinephrine (NE) release (Volmer, 2005). Actions on the peripheral nervous system (PNS) include inhibition of acetylcholine sensitive nerve depolarization at postsynaptic junctions and motor end plates. Respiratory depression is caused by chemoreceptor suppression by barbiturates. This effect is more marked in cats, where the reticular formation governs medullary control of respiration. Control of respiratory activity is believed to be more complex in other species.

Barbiturates cause hypotension and secondary anuria (Branson, 2001; Volmer, 2005). Increased heart rate is believed to be governed by arterial pressoreceptors. The effects of barbiturates on levels of sodium, potassium and calcium in cardiac myocytes produce a change in cardiac contractility. Hypothermic animals are predisposed to ventricular fibrillation with barbiturates. Fibrillation is reported in 100% of hypothermic animals given pentobarbital and 50% of those given thiopental.

### Clinical signs

Onset of clinical signs depends on the route of exposure, the barbiturate involved and the presence or absence of food in the stomach. Animals that have ingested short-acting barbiturates usually have clinical signs within 30 minutes. If long-acting barbiturates were ingested, the first effects might not be observed for an hour

(Kisseberth and Trammel, 1990). The time to onset of clinical anesthesia is doubled if phenobarbital is given to an animal with food in the stomach versus an empty stomach, or if contaminated carrion is ingested. Duration of effects is also variable, as alluded to previously, and dependent on the agent involved, species of animal, nutritional status, age, sex and weight. The duration of a given barbiturate is expected to be prolonged in greyhounds, which have less adipose tissue for the drug deposition.

The predominant signs of barbiturate intoxication are profound CNS depression and anesthesia (Humphreys *et al.*, 1980; Kisseberth and Trammel, 1990; Volmer, 2005). Animals usually present with severe ataxia, weakness, disorientation and loss of deep tendon reflexes. Hypothermia is common and is associated with cardiac dysrhythmia in humans and dogs. The pulse is rapid and weak and severe respiratory depression may lead to cyanosis and death.

Certain preexisting conditions enhance the effects of barbiturates such as renal failure, uremia and decreased rate of excretion. Barbiturates can accelerate liver damage in an individual with preexisting liver disease. Allergic reactions to barbiturates have been reported.

### Treatment

Decontamination for recent exposures, monitoring and symptomatic and supportive therapy are the basis of treatment for barbiturate overdose. Respiratory function, cardiac function and body temperature are closely monitored (Kisseberth and Trammel, 1990; Branson, 2001; Volmer 2005). Emetics are given only to the *asymptomatic* animal if it is soon after ingestion. Gastric lavage after intubation is more appropriate in the animal presenting with CNS depression. Repeated doses of activated charcoal function to decrease the biological half-life of barbiturates. A cathartic such as sorbitol can be added, but magnesium-containing cathartics such as magnesium sulfate (Epsom salt) should be avoided because they can enhance CNS depression. Use of intravenous lipid emulsion would be likely to decrease the bioavailability of highly lipid soluble barbiturates and minimize clinical signs.

Monitoring and control of body temperature is essential to prevent ventricular fibrillation and decrease the duration of the clinical signs. Intubation and assisted ventilation are required when marked respiratory suppression is noted. Fluid therapy is often needed to maintain cardiac and renal function. Alkaline diuresis has been used to increase the rate of excretion of some barbiturates, but is ineffective with short-acting barbiturates. Because tissue partitioning attenuates the effects of barbiturates, it is possible for the patient to relapse as the drug repartitions from the tissues back into plasma. The use of some drugs is contraindicated in the barbiturate

overdose patient. Dextrose, fructose, lactate, pyruvate and glutamate can increase partitioning of barbiturates into the central nervous system. Epinephrine and isoproterenol cause re-anesthetization after thiopental exposure. Sulfonamides, salicylates and doxycycline increase bioavailability of barbiturates by displacing them from plasma proteins.

Many laboratories can analyze samples such as urine, blood products or tissues for barbiturates. Common techniques include TLC and GC/MS. Over-the-counter drug testing kits for urine have been successful in the detection of barbiturates in canine urine in one study, though these kits are not always reliable in one author's experience (Teitler, 2009).

### Opioids

Opium is produced from *Papaver somniferum*, a poppy, and its use was recorded in the Ebers Papyrus, one of the oldest known medical texts dated around 1500 BC. The unripe seed capsule is incised after the petals have fallen. Material that exudes from the capsule is dried, collected and dried further to produce opium. Powdered opium is 75% inert ingredients, about 10% morphine, the major active alkaloid, 0.5% codeine, and the third major alkaloid is dimethyl-morphine or thebaine, which acts as a convulsant (Branson and Gross, 2001). Laudanum is deodorized tincture of opium and paregoric is camphorated tincture of opium.

Morphine sulfate is a Schedule II drug commonly used medicinally for pain control and sedation. Oxymorphone is a Schedule II morphine derivative approved for use in dogs and cats in the U.S. Oxymorphone is approximately ten times more potent than morphine (Branson and Gross, 2001). Other morphine derivatives include codeine and the more potent hydromorphone, both Schedule II drugs. Heroin is a Schedule I morphine derivative.

Synthetic opioids include methadone, propoxyphene, meperidine and pentazocine, all Schedule III drugs. Butorphanol is Schedule IV. Oxycodone and hydrocodone are common prescription synthetic opioids classified as Schedule II. Fentanyl is formulated into injectable solutions, slow-dissolving sticks for oral transmucosal absorption and patches that release doses of 25, 50, 75 or 100 µg per hour for transdermal absorption. Fentanyl is about 80 times more potent than morphine (Branson and Gross, 2001). Other potent synthetic opioids are alfentanil, sufentanil citrate and etorphine HCl, which is 10,000 times as potent as morphine and used in wildlife capture. These potent drugs are classified in Schedule II.

The morphine derivative heroin is one of the most abused opioids, and use is increasing, due to increased availability and relatively low cost, compared to

prescription opioids (Dumonceaux, 1995; Anonymous, 2011). A recent survey of U.S. high-school students found that 2.5% have used heroin, though another survey stated that only about 1% had used heroin in the past year and up to 25% said it was accessible to them (Latimer and Zur, 2010). A white to dark brown powder, heroin often contains additives such as sugar, starch, powdered milk, quinine or strychnine. Heroin was traditionally injected but insufflation (snorting) and smoking are becoming more popular. Heroin is also available as a black sticky substance termed "black tar heroin," which is dissolved, diluted and injected.

Oxycodone, sold as OxyContin®, Percocet® and in a generic form, is commonly used recreationally. A recent survey found that 9% of U.S. high-school seniors had used prescription opioids recreationally (Latimer and Zur, 2010). Pills are time-released but may be crushed and insufflated or injected in solution. Hydrocodone, sold under various trade names and in formulations with acetaminophen (Vicodin®) is also commonly sold on the illegal drug market. Fentanyl can be produced in clandestine laboratories, and is used intravenously.

Small animal exposure to opioids may be due to accidental ingestion of pharmaceuticals, illegal drugs or occasionally by oral or parenteral dosing with malicious intent (Kisseberth and Trammel, 1990; Volmer, 2005).

### Toxicity

With such a wide variety of opioids, there is much variation in toxicity. The lethal parenteral dose of morphine in dogs is between 110 and 210 mg/kg (Kisseberth and Trammel, 1990; Branson, 2001; Volmer, 2005). The minimal lethal dose for subcutaneous injection of morphine in the cat is 40 mg/kg. The minimum lethal dose of heroin for the dog is 25 mg/kg given subcutaneously. Approximately 0.20 mg/kg heroin causes clinical signs in dogs, including sedation and respiratory depression, whereas a dose of 0.58 mg/kg causes increased duration of effects, respiratory difficulty and aggressive behavior with clinical signs lasting up to 8 hours (Garret and Gürkan, 1980). The minimum oral lethal dose of heroin for the cat is 20 mg/kg. Meperidine causes clonic convulsions in cats at a dose of 30 mg/kg (Branson and Gross, 2001).

### Toxicokinetics

Opioids are weakly acidic and absorption after oral dosing is predominantly in the small intestine. There is rapid absorption from the subcutis after subcutaneous injection (Branson and Gross, 2001). Distribution is variable. Heroin is more lipophilic than morphine and more readily crosses the blood-brain barrier (Garrett and Gürkan, 1980). Opioids are also distributed to skeletal muscle, kidney, liver, intestine, lungs, spleen, brain and placenta

(Kisseberth and Trammel, 1990). Opioids are readily metabolized in the liver with a significant first pass effect after ingestion. Phase I metabolism includes hydrolysis, oxidation and N-dealkylation. Approximately 50% of a dose of morphine is conjugated to glucuronide in most species. A notable exception is the cat, accounting in part for the increased sensitivity of this species. The primary glucuronide conjugate is morphine-3 glucuronide, though the metabolically active morphine-6-glucuronide is also produced. Heroin is metabolized in the liver and other tissues and is cleared more rapidly than morphine. Deacetylation produces 6-*o*-acetylmorphine and morphine, which appear in the plasma of dogs within minutes (Garrett and Gürkan, 1980).

Opioids are excreted predominantly as metabolites in the urine. Metabolites may be detected in horse urine for up to 6 days (Branson and Gross, 2001). There is some biliary excretion and enterohepatic cycling. The biological half-life of morphine in cats is about 3 hours. The initial plasma half-life of heroin in dogs is 8 minutes, but the terminal half-life is 80 minutes due to repartitioning from the tissues (Garrett and Gürkan, 1980).

### Mechanism of action

Major opioid receptors are designated  $\mu$ ,  $\delta$  and  $\kappa$  and are believed to be stimulated by endogenous endorphins (Branson and Gross, 2001; Volmer, 2005). The  $\mu$  receptors are activated by endogenous enkephalins. These receptors may be further differentiated into  $\mu_1$  and  $\mu_2$ . Activation of the  $\mu_1$  receptor induces supraspinal analgesia and  $\mu_2$  receptor activation causes spinal analgesia, suppression of respiration and inhibition of gastrointestinal motility. The  $\delta$  receptors are more selective for enkephalins than the  $\mu$  opioid receptors and are involved in spinal analgesia. Activation of  $\kappa$  receptors produces spinal and supraspinal analgesia, sedation and dysphoria. The  $\sigma$  receptor, previously classified as an opioid receptor, does not appear to mediate analgesia.

Opioid receptors are found in the CNS, autonomic nervous system (ANS), gastrointestinal tract, heart, kidney, pancreas, adrenal glands, vas deferens and on the surface of lymphocytes and adipocyte (Volmer, 2005). Opioid receptors in the CNS are concentrated in the amygdala and frontal cortex in the dog, monkey and human where stimulation is associated with CNS depression (Branson and Gross, 2001; Kisseberth and Trammel, 1990). Activation in the cat, swine, goat, sheep, horse or ox may alter dopaminergic or noradrenergic function, leading to excitation. Activation of opioid centers in the chemoreceptor trigger zone in the fourth ventricle of the brain produces emesis. Opioid receptors are present in the brain stem, including the cough centers where they suppress the cough reflex, and the respiratory centers, though initial increases in respiration are

followed by respiratory suppression due to generalized CNS depression. Stimulation of gastrointestinal opioid receptors decreased motility, leading eventually to delayed passage of ingesta, increased water absorption and constipation.

Opioid drugs act as agonists, partial agonists or antagonists. Morphine and related drugs are agonists at  $\mu$  receptors. Naloxone is an antagonist with a high affinity for the  $\mu$  receptors and a low affinity for  $\delta$  receptors (Volmer, 2005). An opioid is classified as a partial agonist if it acts as an agonist at one receptor but an antagonist at another.

### Clinical signs

The clinical effects of opioid drugs are dependent on age (as neonates have an incomplete blood-brain barrier), species and the drug involved. Clinical signs in dogs are similar to those described in humans. Early clinical signs can include transient excitation and rapid respiration, drowsiness and ataxia, decreased pain perception, hypersalivation, vomiting, defecation and urination. Dogs progress to stupor or coma with hypothermia, hypotension, respiratory depression and death (Kisseberth and Trammel, 1990; Dumonceaux, 1995; Branson and Gross, 2001; Volmer, 2005). Other signs include decreased urination and constipation. Signs in dogs given low doses of heroin included early aggressive behavior, brief unconsciousness, weakness, hypersalivation and respiratory difficulty that lasted up to 8 hours (Garret and Gürkan, 1980). Propoxyphene can induce tremors and convulsions in dogs. Cats may present with excitation, aggression, insomnia and hyperthermia as well as increased pain threshold. Cats are highly resistant to the emetic effects of opioids. Horses, ruminants and swine also exhibit CNS stimulation. Clinical signs in rabbits depend on the drug used: morphine induces hypothermia whereas apomorphine induces hyperthermia.

### Treatment

The basis of treatment for opioid exposure is early decontamination, symptomatic and supportive care, and the judicious use of opioid antagonists. Induce vomiting in animals presenting immediately after ingestion of narcotics if they have not already vomited and no contraindications exist. If large doses are ingested and contraindications against emetic use are present, enterogastric lavage on the anesthetized and intubated animal can be performed to evacuate the stomach and instill activated charcoal and cathartics. Decontamination is likely to be effective for several hours after ingestion due to decreased gastrointestinal motility. Animals must be monitored closely for respiratory dysfunction, the most common cause of death in opioid overdoses. Assisted

ventilation is often necessary. Maintain body temperature and treat seizures with diazepam.

The opioid antagonist Naloxone<sup>®</sup> is used to treat severe CNS or respiratory depression. Naloxone can be given parenterally at a dose of 0.01 to 0.02 mg/kg and repeated as necessary, since it has a very short half-life. Patients that fail to respond to a 10 mg dose of Naloxone<sup>®</sup> are unlikely to respond to a higher dose.

Testing of urine or plasma for opioids is available at some diagnostic laboratories. Over-the-counter drug tests kits have been used with variable success to detect opioids in canine urine (Teitler, 2009).

### Other CNS depressants

Other drugs may have depressant activities on the central nervous system. Two commonly used "club drugs" are discussed below: flunitrazepam and GHB. Both are often used by assailants to sedate potential victims, thus there is potential for their use on guard dogs.

#### Flunitrazepam

Flunitrazepam is not sold in the United States but is available in more than 60 countries, including many in Europe and Latin America, as Rohypnol<sup>®</sup>, Narcozep<sup>®</sup>, and under other trade names, as a sedative. Rohypnol<sup>®</sup> has gained notoriety as the "date rape drug" and is sold as tablets imprinted "Roche 1" and "Roche 2" designating their manufacturer and milligram dosage. Tablets may be crushed and insufflated or dissolved in a drink intended for an unsuspecting victim (Smith *et al.*, 2002; Anonymous, 2011). Blue coloring has been added to these pills to reduce the potential for this use (Smith *et al.*, 2002; Rimsza and Moses, 2005). Street names include "roofies" or "rophies," "Roche" or "la rocha," "Mexican valium," "forget me pills," "Rope" and "R2." Injectable forms of flunitrazepam are also available.

Animals that have ingested flunitrazepam should be monitored closely for respiratory and CNS depression, changes in heart rate and body temperature fluctuations. If ingestion was recent and there is not yet evidence of CNS depression, emetics can be given followed by activated charcoal and cathartics to help minimize absorption. Gastric lavage can be performed on the intubated patient who has ingested a large dose and presents with severe CNS depression. Analysis is available at some laboratories for flunitrazepam, but doses are often quite low and urine must be collected soon after ingestion.

#### GHB

Another popular "club drug" that has been associated with date rape is GHB. This compound is a derivative of GABA and is present in the body under normal

conditions. Synthetic GHB can be produced in clandestine laboratories. It was sold as a nutritional supplement for body builders at one time, and is currently used to treat narcolepsy. Industrial solvents  $\gamma$ -butyrolactone (GBL) and 1,4-butanediol (BD) are metabolized to GHB. BD is available in printer ink cartridges and has been sold as a supplement at health food stores (Smith *et al.*, 2002; McDonough *et al.*, 2004; Anonymous, 2011). BD was also used as a substitute for 1,5-pentanediol in the production of a children's craft product called "Aqua Dots" in the U.S. and "Bindeez" in Australia (Suchard *et al.*, 2009). The substitution was made in 2007 and resulted in clinically affected children. GHB is most commonly sold as a clear liquid in small vials and added to bottled water (Smith *et al.*, 2002; Rimsza and Moses, 2005). Street names include "Liquid X" or "liquid ecstasy," "soap" or "salty water" due to the flavor of the product, "easy lay," "Georgia homeboy," "grievous bodily harm," "G," "goop," "gib" or "scoop."

GHB receptors are present in the hippocampus, cortex and other areas of the brain (McDonough *et al.*, 2004). GHB is involved in regulation of sleep cycles, body temperature, memory, glucose metabolism and dopamine levels (Smith *et al.*, 2002). GHB can also be converted back to GABA. Human death has been reported at an oral GHB dose of 5.4 g, but some patients have survived doses of 29 g. The LD<sub>50</sub> for rodents and rabbits is approximately 2 g/kg. GHB is rapidly absorbed from the gastrointestinal tract and, because it is highly lipophilic, it readily crosses the blood-brain barrier. GHB is rapidly metabolized to carbon dioxide though 2 to 4% of a given dose can be excreted in the urine (Smith *et al.*, 2002; Gable, 2004). Half-life is dose dependent.

Clinical signs attributed to GHB usually occur within half an hour of ingestion and include euphoria, reduced anxiety and drowsiness. CNS depression sometimes progresses to loss of motor control, unconsciousness and respiratory depression (Smith *et al.*, 2002; McDonough *et al.*, 2004; Rimsza and Moses, 2005). Clinical signs reported in children ingesting "Aqua Dots" were vomiting, ataxia and coma (Suchard *et al.*, 2009). Seizures have been reported, and bradycardia and hypothermia are reported in nearly a third of overdose patients.

Treatment consists of decontamination of the intubated patient with either gastric lavage, after large ingestion, or activated charcoal – *emetics are contraindicated* due to the rapid onset of CNS depression – and close monitoring of respiratory, cardiovascular and CNS function, and body temperature. Supportive care is instituted based on clinical signs. Seizures have been treated with benzodiazepines. Patients who appear stable should be monitored for at least 8 hours (Smith *et al.*, 2002). GHB is difficult to analyze for and results are difficult to interpret because this compound is rapidly metabolized and normally present in the body.

## STIMULANTS

The major illicit drugs classified as stimulants are cocaine and the amphetamines. Cocaine is a plant alkaloid and amphetamines are a large group of compounds, including prescription drugs such as methylphenidate, sold as Ritalin®, and methamphetamine, which is produced in clandestine laboratories. Stimulants in general act on the ANS, usually on adrenergic receptors. Popular "club drug" 3,4-methylenedioxymethamphetamine (MDMA), or "ecstasy," also has significant action on serotonin receptors. Various legally available compounds act as stimulants through various mechanisms. These include nicotine, caffeine and related compounds, and are discussed elsewhere in the text. Areca alkaloids, described below, are commonly used as stimulants across much of Asia and are available in some parts of the U.S. and Europe.

### Cocaine

Cocaine is the natural alkaloid of the shrubs *Erythroxylon coca* and *E. monogynum*, originally from the Andes Mountains in South America, most commonly grown in Bolivia, Peru and Columbia (Queiro-Neto *et al.*, 2002; Volmer, 2005; Anonymous, 2011). Traditionally, *E. coca* leaves are brewed into tea by those native to the Andes Mountains, who share this delightful beverage with unsuspecting tourists in order to counter the effects of the high altitude. Cocaine is a Schedule II drug used for topical anesthesia and vasoconstriction of mucous membranes (Kisseberth and Trammel, 1990). It may be second only to marijuana in illegal consumption in the U.S. (Dumoncaux, 1995; Queiro-Neto *et al.*, 2002; Vitale and van de Mheen, 2005). According to surveys in the 1980s, approximately 15% of the U.S. population had tried cocaine (Kabas *et al.*, 1990). Recent surveys of high-school students in the U.S. found that 5 to 6.4% had used cocaine (Eaton *et al.*, 2010; Latimer and Zur, 2010).

Cocaine is sold as a powdered white salt, cocaine HCl, ranging in purity from 12 to more than 60% (Kisseberth and Trammel, 1990). It is diluted with inert ingredients such as lactose, inositol, mannitol, corn starch or sucrose, or with active compounds including procaine, lidocaine, tetracaine, caffeine, amphetamine or quinine. Recently, contamination of cocaine with levamisole has been associated with severe adverse effects in users, including agranulocytosis and vasculitis (Buchanan *et al.*, 2010; Wiegand, 2010). The water soluble salt can be injected, ingested or insufflated (Rimsza and Moses, 2005; Anonymous, 2011). Common street names for cocaine HCl include "bernies," "blow," "C" or "big c," "coke," "girl" or "white girl," "gold dust" or "star dust,"

"her," "lady" or "white lady," "nose candy," "snow" or "toot."

Cocaine HCl is converted to the free alkaloid by dissolving it in a basic solution which is boiled to precipitate the alkaloid. The dry precipitate is broken into "rocks" which are 75 to 90% pure, but are often diluted with inert ingredients or active compounds such as procaine, lidocaine, amphetamines, heroin, caffeine, phencyclidine, ergot alkaloids and strychnine. The free base readily vaporizes with heat and the smoke is inhaled, though it may be taken orally. This form of cocaine is termed "crack" because of the sound produced when it is heated, but it is sometimes called "bedrock," "beamers," "BJ's," "bolo," "crank," "crystal," "flake," "ice," "jelly beans," "rock," "rooster," "space," "tornado" or "24/7."

Exposure to illicit cocaine is most likely to affect dogs, particularly police dogs, but athletic horses are sometimes dosed with cocaine to improve performance (Dumoncaux and Beasley, 1990; Kisseberth and Trammel, 1990; Frazier *et al.*, 1998; Queiroz-Neto *et al.*, 2002; Kollias-Baker *et al.*, 2003; Volmer, 2005).

### Toxicity

The LD<sub>50</sub> for cocaine in dogs is 3 mg/kg IV, and the LD<sub>99</sub> is 20 mg/kg IV. Dogs can tolerate two to four times the above doses if given PO. The minimum lethal dose in cats is approximately 7.5 mg/kg IV or 16 mg/kg subcutaneous (SC). Horses given 50 mg of cocaine IV showed no clinical signs, but performance was enhanced at 200 mg (Kollias-Baker *et al.*, 2003).

### Toxicokinetics

Cocaine is highly lipophilic and readily absorbed from all mucosal surfaces, including those of the nose, oral cavity, gastrointestinal tract, and alveoli. Approximately 20% of an ingested dose is absorbed. Peak plasma concentrations appear between 15 minutes and 2 hours after ingestion and cocaine readily crosses the blood-brain barrier. The neurological effects of cocaine and crack last for 15 to 20 minutes after insufflating or 5 to 10 minutes after smoking recreational doses.

Cocaine undergoes hydrolysis by plasma esterases to water soluble metabolites benzoylecgonine, ecgonine methyl ester and others (Queiroz-Neto *et al.*, 2002). Hepatic esterases and demethylating enzymes play a role in cocaine metabolism (Kisseberth and Trammel, 1990; Volmer, 2005). Up to 20% of a dose of cocaine is excreted unchanged in the urine. Benzoylecgonine and ecgonine methyl ester are the primary metabolites excreted in the urine of most mammals in both conjugated and unconjugated forms (Kollias-Baker *et al.*, 2003). Other metabolites include norcocaine, benzoylecgonine, norecgonine and ecgonine. Kollias-Baker *et al.* (2003) found cocaine in the urine for up to 24 hours

when horses were dosed sublingually with 2.5 mg. Larger doses are detectable for a few days.

### Mechanism of action

Cocaine increases release of catecholamines and blocks reuptake of NE, serotonin and dopamine, leading to increased neurotransmitter concentrations at synaptic junctions (Kisseberth and Trammel 1990, Volmer, 1995; Queiroz-Neto *et al.*, 2002; Vroegop *et al.*, 2009). NE regulates thalamic effects on appetite, body temperature and sleep. Cocaine also influences the endogenous opiate system. Local anesthetic actions occur through inhibition of membrane sodium ion channels.

Cardiac effects are often associated with IV dosing of cocaine (Kabas *et al.*, 1990; Kisseberth and Trammel, 1990). Cocaine acts directly on myocardium by blocking sodium ion channels, thus causing conduction disturbances and prolonged R waves. Cocaine increases calcium concentrations within cardiac myocytes and can promote depolarization during the diastolic interval leading to ventricular fibrillation. Cocaine slows conductance at the bundle of His. Oxygen demand is increased within the myocardium but constriction of the coronary vasculature leads to hypoxia and infarction (Kabas *et al.*, 1990; Volmer, 2005; Vroegop *et al.*, 2009).

### Clinical signs

Clinical signs of cocaine toxicosis are associated with CNS stimulation, sometimes followed by depression (Kisseberth and Trammel, 1990). Signs in dogs include hyperactivity, hyperesthesia, tremors, seizures and death. Other reported signs are mydriasis, hypersalivation and vomiting. Cardiac changes are consistently reported. Dogs dosed IV with cocaine had increased heart rate, cardiac output and mean arterial pressure (Catravas and Waters, 1981). Electrocardiographic changes include increased duration of QRS complexes and P-wave abnormalities (Llera and Volmer, 2006). Death was attributed to hyperthermia, secondary to increased muscular activity and peripheral vasoconstriction (Catravas and Waters, 1981; Dumoncaux and Beasley, 1990; Dumoncaux, 1995; Frazier *et al.*, 1998; Vroegop *et al.*, 2009). Frazier *et al.* (1998) reported a body temperature of 105°F (40.56°C) in one dog. Respiratory and cardiac arrest, the latter attributed to coronary vasospasm, have also been implicated as cause of death. Lactic acidosis, hypoglycemia or hyperglycemia, and elevated creatinine phosphokinase have been reported.

Queiroz-Neto *et al.* (2002) reported mild clinical signs in horses given low IV doses of cocaine: increased alertness, irritability, muscle tremors, vocalization and stereotypical behaviors like head-bobbing and pawing at the ground. Cribbing was reported at higher doses. Most horses defecated within 10 minutes of dosing and recovered within

20 minutes. Lesions reported in dogs include subendocardial and epicardial hemorrhage, degeneration of cardiac myofibers, coronary vasoconstriction, pericardial effusion and pulmonary hemorrhage.

### Treatment

Early decontamination of dogs suspected of recently ingesting cocaine has been recommended, but is likely to have limited effects because the drug is absorbed extremely rapidly (Dumonceaux and Beasley, 1990; Dumonceaux, 1995). Furthermore, emesis is likely to induce seizures (Volmer, 2005; Llera and Volmer, 2006). Sedation and gastric lavage in the patient who has ingested a large quantity of cocaine is a safer method of decontamination. Activated charcoal and a cathartic can be given orally. Police dogs that have ingested bags of cocaine require cautious endoscopic or surgical retrieval to prevent rupture or obstruction. Surgically implanted bags must be removed with equal caution and secondary infection treated as necessary. Because cocaine is highly lipophilic, intravenous infusion of lipid emulsion is likely to decrease the bioavailability and clinical effects of cocaine.

Symptomatic and supportive care includes maintaining body temperature, acid-base and electrolyte status, and monitoring cardiac and respiratory function. Body temperature may be maintained by use of a cool environment, cool fluids, cool bath, wet towels, fans or cool water enemas, but avoid inducing shivering, which will increase body temperature. Decreased stress also prevents hyperthermia.

Seizure control also prevents hyperthermia. Diazepam has been used to decrease seizure activity; however, two out of six animals in one study that had an apparent favorable response to diazepam died within 72 hours (Catravas *et al.*, 1977). Barbiturates are recommended to treat refractory seizures. Chlorpromazine given before cocaine dosing was effective experimentally to reduce severity of seizures, maintain blood pH, maintain body temperature, decrease heart rate and blood pressure, and prevent arrhythmias (Catravas and Waters, 1981). Affected animals require respiratory support, including intubation and mechanical ventilation, for severe or prolonged respiratory depression. Cardiac signs such as tachycardia are usually short-lived. Intravenous fluids with sodium bicarbonate are likely to be adequate to decrease electrocardiogram changes and risk of ventricular arrhythmia development. Treatment of *life-threatening* cardiac arrhythmia with beta-blockers such as propranolol has been recommended, but pretreatment of dogs with propranolol before cocaine injection did not increase survival. Beta-blockers are known to produce systemic hypertension (Vroegop *et al.*, 2009).

Urine and plasma are routinely tested for cocaine at many laboratories. Thin-layer chromatography and

immunoassays may be used with confirmation by gas chromatography/mass spectroscopy. Over-the-counter test kits are available to test for cocaine in urine, but their usefulness to the veterinarian has yet to be determined.

### Amphetamines

The term "amphetamine" refers specifically to  $\alpha$ -methylphenylethylamine, a Schedule II drug, but the term is often used to describe various derivatives. The term "amphetamines" (plural) is used here to describe a group of related compounds unless specified otherwise. Common amphetamines include the Schedule II drug methamphetamine and Schedule I drugs 2,5-dimethoxy-4-methylamphetamine ("DOM," "STP"), 2,5-dimethoxy-4-bromoamphetamine ("DOB"), methylphenidate, 4-methylaminorex (4MA) and 3,4-methylenedioxy-N-ethylamphetamine (MDEA). The "designer drug" 3,4-methylenedioxymethamphetamine (MDMA, "ecstasy") has some unique characteristics and is discussed separately below.

Historically, amphetamines were used by veterinarians for the stimulation of medullary respiratory centers in order to increase respiratory rate and depth in animals (Adams, 2001). These drugs are not currently used in veterinary medicine. Physicians have used amphetamines to control appetite in obese patients, to treat narcolepsy, depression, alcoholism and, counter-intuitively, to control hyperkinetic behavior in children. Most are sold as tablets or capsules, which may be sustained release (Kesseberth and Tremmel, 1990). A recent study found that 5% of 8th grade students in the U.S. and 7% of high-school students surveyed had used amphetamines in the past year (Latimer and Zur, 2010).

Amphetamines on the illegal market are sold as "bennies," "dex" or "dexies," "speed" or "uppers." Prescription products may find their way to the illegal market, but many "designer" amphetamines such as methamphetamine are created in clandestine laboratories. Crystal methamphetamine, called "ice" or "glass," may be smoked, powdered methamphetamine, termed "crank" or "meth," may be dosed intravenously, orally or insufflated (Rimsza and Moses, 2005; Anonymous, 2011). "Yaba" contains methamphetamine and caffeine. One survey found that about 4% of U.S. high-school students have used methamphetamine (Eaton *et al.*, 2010). Other "designer" amphetamines include 4-methylaminorex, sold as "euphoria," "U4EUH," or "ice," MDEA, sold as "Eve," methylcathinone (see Khat) and MDMA. Drug dealers may combine amphetamine with inert or other active ingredients, or may substitute other drugs such as heroin, cocaine or phenylethylamine.

Accidental ingestion of prescription amphetamines is the most likely exposure risk for companion animals.

Potential exists for exposure of companion animals to illegal drugs. Illegal doping may occur in horses.

### Toxicity

Catravas *et al.* (1977) found that 10 mg/kg IV amphetamine killed dogs within 3 hours. LD<sub>50</sub>s for orally administered amphetamine sulfate and methamphetamine in the dog are 20 to 27 mg/kg and 9 to 100 mg/kg, respectively (Diniz *et al.*, 2003; Volmer, 2005).

### Toxicokinetics

Absorption of amphetamines through the gastrointestinal system is usually rapid, though it is slower with sustained release products (Dumonceaux and Beasley, 1990; Kesseberth and Trammel, 1990; Dumonceaux, 1995; Volmer, 2005). Methamphetamine absorption is more rapid by insufflation with onset of clinical signs in 2 to 5 minutes, whereas the onset after PO dosing is 15 to 20 minutes (Anonymous, 2011).

Peak plasma concentrations of amphetamine occur 1 to 3 h after ingestion, unless a sustained release product was ingested. Amphetamines are highly lipid soluble and readily cross the blood-brain barrier (Volmer, 2005). Concentrations in the cerebral spinal fluid may be 80% of those found in the plasma (Kesseberth and Trammel, 1990). Methamphetamine has increased partitioning to the CNS compared to other amphetamines (Rimsza and Moses, 2005). Amphetamine is also distributed to the kidneys, liver and lungs, with negligible storage in the adipose tissue (Baggot and Davis, 1972).

There is significant hepatic metabolism of amphetamines. The two major pathways are hydroxylation and deamination. Deaminated products may be oxidized and conjugated to glycine (Baggot and Davis, 1972). Active metabolites may be produced. Amphetamine and its metabolites are excreted primarily in the urine and minimally in the bile. About 8% of an amphetamine sulfate dose is excreted unchanged in the urine in swine and 30% in dogs. Rate of excretion is significantly increased as urine pH declines (Baggot and Davis, 1972; Kesseberth and Trammel, 1990; Volmer, 2005). Amphetamine is almost completely eliminated within about 6 hours in dogs with an average urinary pH of 7.5, and in 3.3 h if the urinary pH averages around 6.0.

### Mechanism of action

Questions remain concerning the mechanism of action of amphetamines. Sympathetic central and peripheral effects are due to direct actions on  $\alpha$  and  $\beta$  adrenergic receptors, increased release of catecholamines, particularly norepinephrine, inhibition of monoamine oxidase (MAO) and inhibition of catecholamine reuptake (Kesseberth and Trammel, 1990; Adams, 2001;

Diniz *et al.*, 2003; Volmer, 2005; Llera and Volmer, 2006). Amphetamines may promote serotonin and dopamine release and act directly on dopamine receptors.

### Clinical signs

Common clinical signs of amphetamine toxicosis in animals include mydriasis, hyperactivity, restlessness, tremors and seizures, and occasionally ataxia and depression. Hyperthermia may be secondary to seizures and peripheral vasoconstriction. Tachycardia and ventricular premature contractions, hypertension, or occasionally hypotension, have also been observed. Other signs are mydriasis, hypersalivation and vocalization.

Reported causes of death in amphetamine overdosed dogs include disseminated intravascular coagulation secondary to hyperthermia and respiratory failure (Davis *et al.*, 1978; Diniz *et al.*, 2003). Cerebrovascular hemorrhages due to hypertension, hypoglycemia, lactic acidosis and cardiac failure have all been implicated as the cause of death after amphetamine overdose (Catravas *et al.*, 1977).

Serum chemistry abnormalities in addition to lactic acidosis and hypoglycemia that have been reported with amphetamine overdose include hyperkalemia, hyperphosphatemia and elevated liver enzymes such as alanine transaminase, alkaline phosphatase and aspartate transaminase (Catravas *et al.*, 1977; Diniz *et al.*, 2003; Llera and Volmer, 2006). Rhabdomyolysis is evident in the presence of increased creatine kinase, myoglobinuria, and there is evidence of renal failure (Kesseberth and Trammel, 1990; Diniz *et al.*, 2003). Lesions in experimental dogs dosed with amphetamines include subendocardial and epicardial hemorrhage and myocardial necrosis.

Low doses of amphetamine given to horses caused increases in heart rate during rest and exercise, increased blood pressure, second degree AV block and premature ventricular contractions (Smetzer *et al.*, 1972).

### Treatment

The prognosis for animals that have ingested amphetamines depends on the dose, time between exposure and presentation, and severity of clinical signs. Gastrointestinal decontamination should be initiated in animals that present within 2 h of ingestion (Kesseberth and Trammel, 1990; Dumonceaux, 1995). Rapid onset of clinical signs may preclude the use of emetics. Gastric lavage of the sedated animal may be warranted if large doses were ingested. Activated charcoal and a cathartic help prevent absorption, but repeat dosing is necessary for sustained release products.

Animals should be monitored closely for neurologic signs, hyperthermia, cardiac arrhythmias or respiratory insufficiency. Baseline serum chemistries should be taken to monitor for hypoglycemia, electrolyte

abnormalities, lactic acidosis, myoglobinuria, liver and kidney damage, etc.

Minimal external stimulation helps to prevent seizure activity. Diazepam may paradoxically exacerbate the clinical signs of many amphetamines (a possible exception is MDMA, see below) and is thus contraindicated (Volmer, 2005). Chlorpromazine given at 10 to 18 mg/kg IV was determined by Catravas *et al.* (1977) to prevent death in experimental dogs dosed with amphetamine when given early in the progression of clinical signs. Treatment decreased hyperthermia, convulsions, hypertension and heart rate. Normal respiration was maintained. Haloperidol at 1 mg/kg IV also decreased the clinical effects of amphetamines on body temperature, blood pressure, heart rate, respiration and decreased convulsions in experimental dogs. Chlorpromazine and haloperidol block  $\alpha$ -adrenergic and dopaminergic receptors. Short-acting barbiturates have also been recommended for treatment of amphetamine-induced seizures.

Cool IV fluids, ice packs, fans, cool water baths or cool moist towels, or gastric lavage with cool water can be used to treat hyperthermia. However, the shivering response may increase body temperature (Smith *et al.*, 2002).

Cardiac arrhythmias in the amphetamine overdose patient may resolve with treatment of central nervous signs (Smith *et al.*, 2002; Diniz *et al.*, 2003). Propranolol has been found to decrease the heart rate and blood pressure in experimental dogs given amphetamines, but did not improve survival (Catravas *et al.*, 1977). The use of  $\beta$ -blockers may lead to  $\alpha$ -receptor-mediated vasoconstriction and spasms of the coronary artery. Lidocaine, procainamide or amiodarone have been recommended to treat ventricular arrhythmias.

Urinary acidification with ascorbic acid or ammonium chloride increases amphetamine excretion but should not be attempted in the presence of acidosis or rhabdomyolysis, or if acid-base status cannot be monitored. Treatment of acidosis and rhabdomyolysis involves fluid diuresis and alkalinization. Respiratory support is sometimes required (Liechthi *et al.*, 2005). Treatment of hepatic damage with *N*-acetylcysteine has been recommended but the effectiveness is not known.

Urine or plasma samples may be tested for amphetamines at many diagnostic laboratories. Thin-layer chromatography is commonly used, and immunologic assays are available for some compounds. Gas chromatography and mass spectroscopy may be used for confirmation. There has been some success using over-the-counter drug test kits to detect amphetamines in canine urine (Teitler, 2009).

## Other stimulants

MDMA, sold as "ecstasy," is a common illegal club drug and will be discussed in some detail. Laws vary between

countries and states as to the legality of the herbal stimulant Khat and the related synthetic compounds mephedrone, and methylenedioxypyrovalerone, which have become common in the U.S. where they are sold in certain products with innocuous sounding names like "bath salts." Many legally available compounds are commonly used as stimulants. These include nicotine from tobacco products, methylxanthines such as caffeine, theobromine and theophylline found in common food and drink products, and alkaloids of the areca nut, present in betel quid. The latter compounds will be addressed briefly.

## MDMA

MDMA, more frequently known as "ecstasy," is a Schedule I drug. MDMA was used as an appetite suppressant and in psychotherapy (Smith *et al.*, 2002). The drug has shown some promise in the treatment of Parkinson's disease and post-traumatic stress disorder, but there are no accepted medical uses at this time (Morton, 2005). Currently, MDMA is one of the most popular club drugs in the U.S. and use increased 70% worldwide between 1995 and 2001 (Anonymous, 2011). A survey of U.S. students found that 5 to 6.7% of students have used MDMA in high school and 2% of 8th graders had used it (Eaton *et al.*, 2010; Latimer and Zur, 2010).

MDMA has been sold under numerous different names, a short list of which includes "Adam," "Batman," "bibs," "blue kisses," blue Nile," "charity," "clarity," "Debs," "decadence," "E," "Eve," "go," "happy pill," "hug drug," "lover's speed," "M," "roll" or "rolling," "Scooby snacks," "X" and "XTC." Tablets containing 50 to 150 mg MDMA are often brightly colored with pressed images such as product logos, butterflies, smiley faces, numbers or letters. Less commonly encountered are the powdered or capsule forms. "Ecstasy" tablets tested in Europe during the 1990s only contained 50% MDMA, on average (Libiseller *et al.*, 2005). Those tested in the U.S. averaged 83% MDMA (Anonymous, 2011). Other common ingredients included ketamine, methamphetamine, MDA and MDEA.

The LD<sub>50</sub> of MDMA in rats is between 160 and 325 mg/kg PO. Dogs given 15 mg/kg MDMA showed severe clinical signs and one of six of the dogs died (Frith *et al.*, 1987). MDMA is metabolized in the liver by N-demethylation to the active metabolite MDA (Smith *et al.*, 2002).

MDMA is structurally similar to amphetamines and mescaline, which may explain some of the clinical effects (Lyles and Cadet, 2003). MDMA increases neurotransmitter release, including serotonin, dopamine and NE (Smith *et al.*, 2002; Morton, 2005; Rimsza and Moses, 2005). Hallucinogenic effects have been attributed to serotonin release and inhibition of reuptake. This drug also inhibits MAO. MDMA directly binds to certain receptors, including 5-HT<sub>2</sub> receptors,  $\alpha_2$ -adrenergic receptors, M<sub>1</sub> muscarinic receptors and H<sub>1</sub> histamine

receptors, with less affinity for 5-HT<sub>1</sub>, dopamine, M<sub>1</sub>,  $\alpha_1$  and  $\beta$  receptors.

Frith *et al.* (1987) described the effects of MDMA given to dogs at increasing oral doses. Clinical signs began after about 45 minutes and continued for 6 to 8 hours. Dogs given low doses (3 mg/kg) most frequently showed signs of hyperactivity and mydriasis. Dogs given 9 mg/kg also became tachypneic with hypersalivation and circling behavior. One of six dogs given 15 mg/kg MDMA died after showing clinical signs that included vocalization, aggression, convulsions and front limb paralysis.

Onset and duration of clinical signs are similar in humans, though onset is more rapid with insufflation (Smith *et al.*, 2002; Rimsza and Moses, 2005). Mydriasis, delirium confusion, agitation, bruxism, tremors, seizures and loss of consciousness have been reported in MDMA users, as have hyperthermia and rhabdomyolysis (Kesseberth and Trammel, 1990; Smith *et al.*, 2002; Liechti *et al.*, 2005; Rimsza and Moses, 2005). Cardiovascular changes may include tachycardia or less commonly bradycardia, AV block and hypertension. A few deaths have been attributed to cardiopulmonary arrest (Liechti *et al.*, 2005) and liver failure (Andreu *et al.*, 1998; Gable, 2004; Rimsza and Moses, 2005; Liechti *et al.*, 2005). Onset of liver failure occurs days to weeks after exposure and the mechanism is not understood, though a hypersensitivity reaction has been suggested in some cases.

Treatment of MDMA exposure consists of appropriate gastrointestinal detoxification, as with amphetamines, and symptomatic and supportive care.

#### **Khat, mephedrone and methylenedioxypyrovalerone**

Khat (*Catha edulis*) is a plant found in East Africa and the Arabian Peninsula. Traditionally, leaves of this shrub have been chewed or consumed as a stimulant, but they are sometimes smoked. The leaves contain cathinone, a DEA Schedule I substance, which breaks down after about 36 hours, and the more stable compound cathine, which is a Schedule IV substance (Anonymous, 2011). Clinical signs associated with khat use include reduced appetite, tachycardia, hypertension and insomnia.

Mephedrone (4-methylmethcathinone) and methylenedioxypyrovalerone (MDPV) are compounds related to cathinone that have increased exponentially in popularity over the past few years. Mephedrone became illegal in the United Kingdom in April 2010, where it sells for approximately 20% of the cost of cocaine and is that nation's fourth most popular drug, after marijuana, cocaine and MDMA (Elwell, 2010). Mephedrone and MDPV are sold in the U.S. as "bath salts," under names such as "Ivory Snow," "Red Dove" and "Vanilla Sky."

Mephedrone and MDPV are snorted or ingested. Clinical signs usually last a few hours, but can last days (Elwell, 2010). Users report euphoria, increased energy

and become talkative. Adverse effects include epistaxis, mydriasis and cardiac arrhythmias. Later, users experience fatigue, dizziness and depression.

#### **Betel quid**

Though not common in most areas of the U.S., alkaloids of the areca nut are believed to be the fourth most commonly used psychoactive substance in the world after caffeine, ethanol and nicotine. It is estimated that 10 to 20% of the world population have access to "betel quid" containing these alkaloids, mostly in South and Southeast Asia and the Asia Pacific regions. These products can also be purchased in U.S. cities with large populations of Asian immigrants.

Palm trees of the genus *Areca* are cultivated in tropical and subtropical areas of the world to produce betel quid (Deng *et al.*, 2001). The nut of this palm tree may be ingested green, ripe and raw, baked, roasted, boiled, fermented or processed with various sweeteners. It is most commonly processed with leaves from the betel shrub, *Piper betle*, and calcium hydroxide. Tobacco and various spices are sometimes added. The betel quid industry is worth hundreds of millions of dollars. Betel quid is produced locally or under trade names such as Supari, Mainpuri tobacco, mawa, pan masala and Gutka. Gutka is illegal in some parts of India.

Alkaloids present in areca nut include arecoline, arecaine, guvacine and guvacoline. These alkaloids bind muscarinic receptors, induce coronary vasospasms and have weak activity on nicotinic receptors in ganglia.

Oral submucosal fibrosis is a preneoplastic disease that is common in young people who use betel quid. Clinical signs seen in inexperienced users and overdoses are more likely to be of interest to the veterinarian and may include mucosal irritation, nausea and vomiting, bronchoconstriction, hypersalivation, lacrimation, urinary incontinence, diarrhea, hypertension or hypotension, tachycardia, acute myocardial infarction and extrapyramidal signs. Most patients given supportive care recover within 24 h, and atropine has not been found to be effective as a treatment in humans (Deng *et al.*, 2001).

## **HALLUCINOGENS AND DISSOCIATIVE DRUGS**

The clinical effects of hallucinogenic and dissociative drugs are unpredictable and dependent very much on the individual and their environment (Nichols, 2004). Many compounds that alter consciousness have been termed "hallucinogens," though some, like marijuana and MDMA, only induce hallucinations under specific circumstances or at very high doses. "Psychomimetic"

is a term used to describe drugs that cause behavioral changes mimicking psychosis, but the value of this term in veterinary medicine is questionable. "Psychedelic" is a term commonly used by the media.

Lysergic acid diethylamide (LSD), a synthetic product similar to natural ergot alkaloids, is a common hallucinogen that acts on serotonin receptors. Hallucinogens with a similar mechanism of action include mescaline and N, N-dimethyltryptamine (DMT), described below. *Psilocybe* spp. and related mushroom species contain the hallucinogen psilocybin. Vomiting was reported after *Psilocybe* spp. mushroom ingestion in a dog (Spoerk, 2005). Behavioral changes in a horse suspected of ingesting *Psilocybe* spp. included fear and extreme aggression with recovery within 48 h (Hyde, 1990). Signs of severe toxicosis in a colt included hyperexcitability, tremors, mydriasis and bruxism. The colt was eventually euthanized due to traumatic injuries and weakness (Jones, 1990). Signs of psilocybin in cats are similar to those described below with LSD (Jacobs *et al.*, 1977). DMT is produced by several plants including *Psychotria viridis*, used to produce a tea known as Ayahuasca in the traditional practices of the indigenous people of the Amazon, *Anadenanthera peregrina* seeds, called yopo by native people of the Amazon rain forest, and *Phalaris* spp. of grass which grow around the world. Leaves of the plant *Salvia divinorum* are legal to possess and are commonly used to produce hallucinogenic effects, though by a unique mechanism described below.

Dissociative anesthetics are so called because they uncouple functions of the brain such as sensory and motor activity, emotion and consciousness, sometimes producing a cataleptic-type state (Branson, 2001). Affected individuals become disconnected from their environment and there is an absence of response to nociceptive stimuli. The synthetic drug phencyclidine is an example of a dissociative agent. Ketamine, a familiar therapeutic drug to most veterinarians, is a dissociative anesthetic and also a popular "club drug."

Several naturally occurring substances are used to produce hallucinogenic effects by various mechanisms. Certain species of mushrooms in the genus *Amanita*, specifically *A. muscaria* and *A. pantherina*, are sometimes intentionally ingested. These mushrooms contain ibotenic acid and muscimol, which bind glutamate receptors. Various plants containing atropine and scopolamine, including *Datura stramonium*, *Atropa belladonna*, *Mandragora officinarum* and *Hyoscyamus niger*, are routinely smoked or ingested (Halpern, 2004). The drug dextromethorphan is used recreationally for its dissociative effects.

## LSD and LSA

Lysergic diethyl amide (LSD) is the most powerful known hallucinogen (Nichols, 2004; O'Shea and Fagan, 2006). The d-isomer of LSD is responsible for the molecule's

effect on the CNS. The story of Albert Hoffman's synthesis and subsequent exposure to LSD is well documented elsewhere. LSD was marketed under the trade name Delysid and used in psychotherapy and for experimental purposes. Though there are no current medical uses for this drug, it has shown some promise for use in the treatment of alcoholism, drug addiction and obsessive-compulsive disorder. After becoming a popular recreational drug, LSD use was banned by the U.S. government in 1966, and it is currently a Schedule I drug (Nichols, 2004; Volmer, 2005).

LSD is a colorless, odorless and flavorless white powder that is usually dissolved in water, then applied to other substances such as blotter paper, microdots, tiny tablets, gelatin squares (termed "window pane" or "window glass"), stamps, gummy bears and other candies, and sugar cubes (Rimsza and Moses, 2005; Volmer, 2005; O'Shea and Fagan, 2006; Anonymous, 2011). Street names for LSD reflect these applications and include "acid," as in "spiked with acid," "blotter" or "blotter acid," "cubes," "dots" or "microdot," "L," "sugar" or "sugar cubes," "trip" or "wedding bells." Use of LSD is declining in the U.S. (Banken, 2004; Nichols, 2005). A recent survey found that 3% of high-school seniors had used LSD in the past 12 months (Latimer and Zur, 2011).

The seeds of *Ipomoea violacea*, the morning glory, contain lysergic acid amide (LSA), which is approximately 1/10th as potent as LSD, at a concentration of 0.02% dry matter (Halpern, 2004). Ingestion of 150 to 300 seeds causes clinical effects in humans (Frohne and Pfänder, 2004; Halpern, 2005; Volmer, 2005). The seed coat is protective, thus seeds must be crushed, germinated or soaked in water for ingestion to be effective. A word of caution to the adventurous: emetics are sometimes added to commercial morning glory seeds. Other sources of LSA include seeds of the Hawaiian baby woodrose, *Argyrea nervosa*, at a concentration of 0.14% dry matter, and endophyte-infected sleepy grass, *Stipa robusta*. *S. robusta* is present in the southwestern U.S.

## Toxicity

The effective dose of LSD for humans is between 0.05 and 0.20 mg. Products sold currently usually contain 0.04 to 0.06 mg and carry less likelihood of an adverse reaction than the pills sold in the 1960s, which could contain up to 0.25 mg LSD. Increasing the dose may produce both quantitative and qualitative differences in the response (Nichols, 2005). Some cats given intraperitoneal (IP) injections of 2.5 µg LSD/kg body weight showed mild clinical signs, and a dose of 50 µg/kg produced significant clinical signs in all cats tested (Jacobs *et al.*, 1972). The IV LD<sub>50</sub> for rats is 16 mg/kg (Volmer, 2005).

## Toxicokinetics

LSD is rapidly absorbed after ingestion in humans (Riordan *et al.*, 2002; Volmer, 2005). Peak plasma

concentrations occur within 6 hours and LSD is approximately 80% protein bound. Metabolism occurs primarily in the liver by hydroxylation and glucuronide conjugation to an inactive metabolite. A dose of LSD is 89% excreted in the feces and the elimination half-life is between 2 and 5h. Clinical effects can persist for 12 hours (Nichols, 2004).

### Mechanism of action

Many “recreational” hallucinogens act primarily as antagonists at serotonin receptors (Volmer, 2005; O’Shea and Fagan, 2006). LSD is structurally similar to serotonin. Actions at the 5-HT<sub>2A</sub> receptor are believed to be responsible for the hallucinogenic effects, though the signaling pathways involved have not been completely elucidated. Affected 5-HT<sub>2A</sub> receptors are located in the pyramidal cells of the prefrontal cortex, the reticular nucleus of the thalamus, and possibly the locus coeruleus, where the effect is to alter sensory processing. LSD and some other hallucinogens also have a strong affinity for the 5-HT<sub>1A</sub>, 5-HT<sub>2C</sub> and other serotonin receptors, but the significance of this is not understood (Nichols, 2004). LSD causes increased release of glutamate in the prefrontal cortex, has a high affinity for dopamine receptors D<sub>1</sub> and D<sub>2</sub>, and shows some affinity for  $\alpha_1$  and  $\alpha_2$  adrenergic receptors (Nichols, 2004; Volmer, 2005).

### Clinical signs

General signs reported in nonhuman animals include disorientation, mydriasis, depression or excitation, and vocalization (Volmer, 2005). Behavioral changes reported in cats given IP injections of LSD included paw flicking, head and body shaking, yawning, chops licking, bizarre sitting and standing positions, falling from their perch, leaping about, compulsive scratching at the litter, pawing at the water, biting objects in the cage, play behaviors including pawing and sniffing objects, tail chasing and “hallucinatory behavior,” described as tracking, staring at, batting at, or pouncing on objects that were not apparent to the observer, frequent defecation and occasionally emesis. Grooming behaviors included rubbing the head with paws, licking, biting and scratching, and were sometimes “incomplete” – the cat would lick or bite the air or stick her tongue out. Rage behavior and vocalization were not seen in these cats (Jacobs *et al.*, 1977). Based on this study, one can only imagine the presenting complaint in a companion animal after accidental exposure to LSD.

### Treatment

Treatment is based on close observation with supportive and symptomatic care. Because absorption of LSD is relatively rapid and effects are self-limiting, gastrointestinal decontamination is unlikely to be beneficial

(Riordan *et al.*, 2002; Volmer, 2005). Clinical signs sometimes persist for up to 12h after ingestion of a large dose. Animals should be kept in a quiet, dark room to minimize sensory stimulation and restraint should be minimized to prevent hyperthermia. Laboratory techniques that have been employed in the detection of LSD include immunoassays, thin-layer chromatography, HPLC and LC/MS.

### Phencyclidine and ketamine

Phencyclidine, 1-(1-phenylcyclohexyl)piperidine, is a Schedule II synthetic drug with more than 80 known analogs. One such analog, ketamine or 2((-o-chlorophenyl)-2-methylamino)-cyclohexanone HCl, has less than 1/10th the potency of phencyclidine and is a Schedule III drug. Phencyclidine was originally used as an anesthetic under the trade names Sernyl for human patients and later Sernylan for veterinary patients. Sernyl, given IV, produces decreased response to nociceptive stimuli with insignificant respiratory and cardiac depression and no loss of corneal, papillary or other reflexes (Branson, 2001). However, Sernyl was associated with postoperative psychosis, dysphoria, delirium, violent behavior and hallucinations (Kisseberth and Trammel, 1990; Pestaner and Southall, 2003; Volmer, 2005; Anonymous, 2011). Sernylan was used in dogs, nonhuman primates, and was the preferred anesthetic for crocodilians (Ortega, 1967; Stunkard and Miller, 1974). Phencyclidine was last used commercially in the United States in 1978.

Phencyclidine is easily synthesized in clandestine laboratories. It is available in powdered or crystal form which may be dissolved in liquids such as water or “embalming fluid,” which contains formaldehyde and methanol, or it may be sold in tablets or capsules. Street products range from 5 to 90% purity and phencyclidine is sometimes substituted for THC, mescaline, LSD, amphetamine or cocaine. Phencyclidine is said to have a distinctive odor (Anonymous, 2011). This drug is frequently sold under the name “PCP” but other terms include “angel dust” or “angel hair,” “boat” or “love boat,” “dummy dust,” “CJ,” “hog” or “hog dust,” “PeaCe Pill,” “rocket fuel,” “stardust,” “whack” and “zombie dust.” “Embalming fluid” is added to cigarettes containing tobacco, marijuana or other leafy material such as parsley, mint or oregano. Names for this type of product include “supergrass,” “amp,” “happy sticks,” “sherm” and “wet sticks.”

Ketamine is not as readily produced by the amateur chemist but is used in veterinary and, less commonly, human medicine. Ketamine is labeled for use in cats and nonhuman primates. It is still used by physicians in pediatrics and in emergency and critical care situations where maintenance of blood pressure and respiration are crucial. Ketamine is an odorless, flavorless liquid which is often dried and crystallized then powdered for illicit use.

Ketamine can be ingested, injected, insufflated, placed into tobacco or marijuana cigarettes and smoked and has been used to "spike" drinks. Street names for ketamine include "cat valium," "green," "jet," "K," "special K," or "vitamin K," "keets," "kit-kat," "super acid" and "super C."

### Toxicity

Phencyclidine given orally at doses of 2.5 to 10 mg/kg produces clinical effects in dogs and doses of 25 mg/kg were lethal in all of six dogs treated (Kisseberth and Trammel, 1990; Volmer, 2005). Given via intramuscular (IM) injection, 2 mg/kg caused muscular incoordination, 5 mg/kg caused immobilization and convulsions in one of five dogs, and 15 mg/kg caused convulsions in both of two dogs treated (Ortega, 1967).

Ketamine has a high therapeutic index in domestic mammals. The sedative dose in cats is 20 mg/kg IM. Doses of 5 to 10 mg/kg IM have produced convulsive seizures in dogs. IV injections of 2 mg/kg produce ataxia in sheep and dissociative analgesia in cattle. Doses of 5 to 15 mg/kg IV caused struggling and vocalization in goats (Branson, 2001). The approximate LD<sub>50</sub> for ketamine in rodents is 600 mg/kg PO (Gable, 2004). Large doses of ketamine do not appear to produce analgesia in chickens or pigeons, but pigeons have gone into respiratory failure after being dosed with 0.11 mg/kg. A dose of 0.05 to 0.1 mg/kg produced anesthesia in parakeets, but 0.5 mg/kg IM was lethal (Branson, 2001).

### Toxicokinetics

Phencyclidine is ionized at gastric pH, thus little is absorbed in the stomach but there is significant intestinal absorption (Kisseberth and Trammel, 1990; Volmer, 2005). Inhaled phencyclidine is well absorbed. The drug is lipophilic, with a wide tissue distribution that includes the CNS, adipose tissue and gastric secretions. The latter leads to recycling and increases the biological half-life. Metabolism is variable between species. In the dog, approximately 68% of a given dose undergoes hepatic metabolism to a monohydroxyl form which is then conjugated for excretion. The remaining 32% is excreted unchanged in the urine. Approximately 88% of a dose of phencyclidine is excreted unchanged in the urine in cats.

Peak plasma concentrations in cats occur 10 minutes after IM injection of ketamine (Branson, 2001; Volmer, 2005). Ketamine is about 50% bound to plasma proteins in horses. It is distributed to the brain, adipose tissue, liver, lung and other tissues. Ketamine undergoes hepatic metabolism via N-demethylation or hydroxylation and glucuronide conjugation to a water soluble metabolite for excretion in the urine. The elimination half-life is approximately 67 minutes in the cat after parenteral dosing, 60 minutes in the calf, 42 minutes in the horse after IV dosing and 2 to 3 hours in the human (Branson, 2001).

### Mechanism of action

How compounds like phencyclidine and ketamine produce dissociative effects is not entirely understood. It is known that these drugs act on sites in the cerebral cortex, thalamus and limbic system (Branson, 2001; Pal *et al.*, 2002; Volmer, 2005). The effects on behavior and cognition in humans may mimic schizophrenia. Phencyclidine and ketamine bind to N-methyl-D-aspartate (NMDA) receptors at a different site than glutamate, the excitatory neurotransmitter, and therefore act as noncompetitive inhibitors. Reuptake of NE, dopamine and serotonin is decreased through inhibition of the biogenic amine reuptake complex. The sympathomimetic effects are associated with changes in heart rate, blood pressure and cardiac output and increased myocardial oxygen consumption. Phencyclidine inhibits  $\gamma$ -aminobutyric acid. Cardiovascular effects are more prominent with ketamine than phencyclidine.

Ketamine induces stage I and stage II anesthesia but not stage III. Ketamine acts on non-NMDA glutamate receptors, dopaminergic receptors, nicotinic receptors, muscarinic receptors and opioid receptors. Analgesic properties may be attributed to the actions of ketamine on opioid receptors. Ketamine binds dopamine receptors in dogs.

### Clinical signs

Dogs dosed with phencyclidine appear depressed at low doses and stimulated at high doses, with the potential for convulsive seizures (Branson, 2001). Onset of clinical effects is within 2 minutes of IV dosing (Ortega, 1967). Signs reported in dogs include muscular rigidity, grimacing facial expression, increased motor activity, head weaving, stereotyped sniffing behaviors, blank staring, incoordination, hypersalivation, nystagmus, opisthotonos, ascending loss of motor function, coma, tonic-clonic convulsions and hyperthermia (Ortega, 1967; Kisseberth and Trammel, 1990; Volmer, 2005). Cardiovascular effects include tachycardia, hypertension and cardiac arrhythmia. Deaths have been attributed to respiratory failure. Signs associated with phencyclidine in swine include muscle tremors and hypersalivation (Jones, 1972). Behavioral changes have been noted in neonates that were exposed during gestation (Branson, 2001). Reported changes in clinical chemistry parameters include acidosis, hypoglycemia, electrolyte imbalances and increased creatine phosphokinase and aspartate transaminase. Postmortem lesions associated with phencyclidine include epicardial and subendocardial hemorrhage and pulmonary congestion and hemorrhage (Kisseberth, 1990; Volmer, 2005).

Pineal, pedal, photic, corneal, papillary, laryngeal and pharyngeal, and other reflexes, are maintained during ketamine anesthesia (Branson, 2001; Volmer, 2005). There are significant species differences in the effects of ketamine. Ketamine increases muscle tone in cats, sometimes

causing forelimb extensor rigidity or opisthotonos. Other signs in cats include mydriasis and fixed staring. Hypersalivation and chops licking are associated with oral dosing. Most cats can sit within 2 hours and recover completely within 10 hours. Ketamine causes excitation in dogs and can produce tonic-clonic seizures. Pulmonary edema was reported in a dog 2 days after anesthesia with ketamine and xylazine. Hypersalivation, apneustic breathing and increased pulse are reported in sheep. Goats salivate, struggle and vocalize but usually recover within 20 minutes of dosing. Nonhuman primates have increased heart and respiratory rates and hypertension.

### Treatment

Prognosis for an animal overdosed with phencyclidine or ketamine is generally good with early intervention, but self-induced trauma and rhabdomyolysis complicate treatment. Cats that have undergone ketamine anesthesia usually recover rapidly and are able to sit up within 2 hours (Branson, 2001). Dogs injected with low doses of phencyclidine (1 mg/kg IM) recovered almost completely in a little over an hour, and at higher doses (5 mg/kg) were able to sit up within 2 hours (Ortega, 1967).

Treatment of phencyclidine or ketamine overdose is generally symptomatic and supportive. Animals must be kept in a dark, quiet room and restraint is to be avoided.

Inducing emesis is of limited use due to the rapid absorption of phencyclidine, but may be attempted in very recent ingestions of large doses if no contraindications exist (Kisseberth and Trammel, 1990). Activated charcoal binds phencyclidine, prevents recycling and is known to reduce mortality in dogs and rats. Repeated dosing of activated charcoal and cathartics is recommended due to enterohepatic cycling. Since these are lipophilic compounds, administering intravenous lipid emulsion may decrease the clinical effects.

Forced diuresis with mannitol or furosemide will increase the rate of clearance. Urinary acidification enhances excretion but is contraindicated in the presence of acidosis or rhabdomyolysis. Electrolyte abnormalities and hypoglycemia should be corrected as necessary.

Body temperature of the patient should be monitored. Cardiorespiratory abnormalities have been reported in some species. Muscle rigidity, hyperactivity and seizures associated with ketamine have been treated successfully with diazepam. Severe seizures require barbiturates or general anesthesia. Phenothiazine tranquilizers are believed to decrease the seizure threshold, exacerbate anticholinergic effects and produce hypotension.

### Other compounds

Mescaline, the active compound in peyote, is a well-studied hallucinogen due to its significance both

culturally and in the illicit drug trade. Salvinorin-A is an agent with hallucinogenic potential that is found in the legal herb *Salvia divinorum*.

### Mescaline

Use of mescaline (3,4,5-trimethoxyphenethylamine) dates back to approximately 8500 BC (Bruhn *et al.*, 2002). It is derived from several species of cactus including *Lophophora williamsii*, the peyote *Echinopsis pachanoi*, the San Pedro cactus, and *E. peruvianus*, the Peruvian torch cactus. The latter two cacti are native to South America and are common ornamental plants. Both can be boiled into a soup for ingestion. Peyote grows in the southwestern U.S. and Mexico and is used legally by indigenous people. A tuberous root grows into the ground and is capped by crowns or "buttons" which are removed. The buttons may contain 1.5% mescaline on a dry matter basis. Buttons can be eaten fresh but are often dried. Dried buttons are chewed, powdered, reconstituted or steeped into a tea. Pickled buttons have caused botulism (Halpern, 2004). Though traditional uses are permitted, mescaline is a Schedule I drug.

Mescaline is well absorbed by oral and parenteral routes in the dog, with maximum plasma concentrations detected within an hour of ingestion. Mescaline concentrations detected in the brain reflect blood concentrations. Renal, hepatic and splenic concentrations are three to six times blood concentrations. Mescaline can be detected in the urine within 30 minutes of exposure and remains detectable for up to 24 hours. Between 28 and 46% of a given dose is excreted unchanged in the urine (Chochin *et al.*, 1950). The mescaline molecule is structurally similar to serotonin and acts on the 5-HT<sub>2A</sub> receptor (Nichols, 2004).

Clinical signs of mescaline intoxication in dogs include vomiting, mydriasis, injection of the conjunctiva, hyperreflexia, chewing motions of the jaw and either excitation and disorientation or profound depression. Dogs are reported to recover from severe depression within 10 hours (Chochin *et al.*, 1950). Signs in humans are fairly similar and may include emesis, especially after ingestion of *Echinopsis* spp. (Halpern, 2004). Other signs that have been reported are mydriasis, sweating, hallucinations, synesthesia, disorientation, incoordination, increased heart rate and blood pressure, and hyperthermia.

### *Salvia divinorum*

*S. divinorum*, known as salvia, is a perennial sage closely related to mint. The plant is native to Mexico and grows in humid, semitropical climates. It is cultivated in California and Hawaii (Anonymous, 2011). The plant is of cultural significance to the Mazatec Indians of Oaxaca, Mexico, where it is used to treat diarrhea, headaches,

rheumatism and semi-magical diseases (Prisinzano, 2005). These indigenous Mexicans either chew the fresh leaves or extract juice. Salvia is also smoked (Frohne and Pfänder, 2005; Prisinzano, 2005). Salvia is a controlled substance in Denmark, Austria and Italy.

Salvia contains various diterpenes, including salvinorins A through F and divinorins A through C. Similar compounds are present in plants of the genus *Coleus*. Biological effects are attributed to salvinorin-A. Salvinorin-A is absorbed through the oral mucosa (Halpern, 2004). Little is known about the metabolism of this compound, but the elimination half-life in non-human primates averages 55.6 minutes (Prisinzano, 2005). Unlike other traditional hallucinogens, salvinorin-A is an agonist at the  $\kappa$  receptor and has no known effect on the 5-HT<sub>2A</sub> receptor. No toxic effects were seen in mice given high doses of salvia. No poisonings have been reported in animals.

## CONCLUSIONS

Toxicoses due to ingestion of illegal substances are infrequently reported in veterinary literature, but anecdotally common. With the high incidence of "recreational" drug use in the United States, occasional companion animal exposures are expected. Exposures are through accidental ingestion of the owner or neighbor's private "stash" or intentional exposure, either with lethal intent or as an attempt to get the pet "stoned." Though companion animals are far more likely to ingest "recreational" drugs, there are documented exposures of cattle and horses to illegally cultivated marijuana and illegal drugs have been used to alter the performance of horses.

There are a large variety of drugs used for recreational purposes, and their actions vary mechanistically, producing a broad range of clinical signs. Treatment requires detoxification and symptomatic and supportive therapy. Rarely are specific antidotes available, though antagonists are available for opioid drugs. Quantity of the drug ingested and severity of clinical signs are important factors for determining treatment regimen and prognosis. Some drugs, however, such as marijuana, can cause severe CNS signs in animals, but have an excellent prognosis with early and appropriate intervention.

# Aluminum

Ramesh C. Gupta

## INTRODUCTION

Aluminum (Al) is the third most abundant element that occurs naturally in the earth's crust. It is released to the environment both by natural processes and from anthropogenic sources. Small amounts of Al are released into the environment from coal-fired power plants, incinerators and roofing and siding materials. In addition, Al and Al-based compounds are used for a variety of purposes, from medicines (such as antacids, buffered analgesics, antidiarrheal agents and anti-ulcerative agents) to explosives and fireworks. Today, the use of Al is on the decline compared to two decades ago, but it is still used in a wide range of products and as a result poses risks to both animal and human health. Under some circumstances, exposure of animals and humans to Al is inevitable. Poisoning in animals by Al is rare, but in several incidents the outcome has been very serious or deadly. Among all Al compounds, Al phosphide is of major concern to animals, because at a low stomach pH, phosphide converts to toxic phosphine ( $\text{PH}_3$ ) gas. Al has been widely studied for its toxicological effects, especially for neurotoxicity, developmental and neurobehavioral toxicity in laboratory animals. This chapter focuses on Al toxicity in animals.

## BACKGROUND

Aluminum (Al) metal is obtained from Al-containing minerals, primarily bauxite. It is silvery-white in appearance and light in weight. Al is a component of beverage

cans, pots and pans, siding and roofing materials and foil. It is also found in products such as antacids, astringents, buffered aspirin, antiperspirants, toothpaste and food additives. In powdered form, Al is used in fireworks and explosives (ATSDR, 2006). Al occurs ubiquitously in the environment in the form of Al oxide, Al chlorhydrate, Al hydroxide, Al chloride, Al lactate, Al phosphate and Al nitrate. Because of a high reactivity Al does not exist as the metal in the environment, instead it combines with other elements such as sodium and fluorine and as complexes with organic matter.

Aluminum (Al) has a predilection for the brain and nervous tissues, therefore it touches every organ in the body via its nerve connections. The implication of Al in the etiology of a neurodegenerative disease like Alzheimer's has been well studied, and its effects at the nuclear, cytoplasmic, cytoskeletal, membrane, synaptic and neurotransmitter levels have been well studied (McLachlan, 1995; Savory *et al.*, 2006; Krewski *et al.*, 2007; Garcia *et al.*, 2010). Al exposure may also promote the onset of Parkinson's disease (Bondy, 2010). Its role has also been established in encephalopathy and amyotrophic sclerosis (Deloncle and Pages, 1997). In dogs, chronic Al exposure and its toxicity is linked to Cognitive Dysfunction Syndrome (CDS) or Doggie Alzheimer's Syndrome. Sometimes, a similar syndrome is observed in cats. These animals exhibit memory loss and personality change, and finally they fail to recognize their owners.

From a toxicological perspective, Al phosphide, which is commonly used as a pesticide, has been encountered in the poisoning of cows. In these cases, a majority of the toxicity comes from phosphine ( $\text{PH}_3$ ) gas which is generated from phosphide in the GI tract. Acute toxicity of

Al in animals is rare, but following subacute or chronic exposure, Al can produce a variety of toxicological effects. Frank *et al.* (1992) reported multifocal polioencephalomyelomalacia in Simmental calves associated with elevated Al levels. Adverse effects due to high Al levels have been observed in many domestic and wild-life species and fish (Allen, 1984; Sparling and Lowe, 1996). Al has also been involved in the etiology of grass tetany (Allen *et al.*, 1980). Since Al readily crosses the blood–brain barrier and the placental barrier, it appears that neurotoxicity and developmental toxicity are of particular concern in relation to Al toxicity (Gupta, 2009; Kumar and Gill, 2009; Domingo, 2011).

## TOXICOKINETICS

Aluminum (Al) is poorly absorbed following either oral or inhalation exposure, and practically none is absorbed following dermal exposure. In general, approximately 0.01–5% of ingested and 1.5–2% of an inhaled dose of Al is absorbed. Bioavailability of Al depends upon its chemical form and particle size (inhalation). For example, Al nitrate has shown to be twice as bioavailable as Al chloride in rats (Yokel and McNamara, 1988). In Wistar rats receiving a single gavage dose of Al hydroxide, Al citrate, Al citrate with added sodium citrate or Al maltonate, the fractional intestinal absorptions were 0.1, 0.7, 5.1 and 0.1%, respectively. In rabbits, following a single oral dose of the water soluble compounds, Al chloride (333mg Al/kg), Al nitrate (934mg Al/kg), Al citrate (1081mg Al/kg) and Al lactate (2942mg Al/kg), Al absorption was 0.57, 1.16, 2.18 and 6.3%, respectively (Yokel and McNamara, 1988). It appears that the oral absorption of Al can vary ten-fold based on chemical form alone, i.e., less absorption for water insoluble forms and more for water soluble forms.

Evidence suggests that following ingestion, Al is primarily absorbed in the duodenum and jejunum. The acidic pH of the stomach may solubilize Al from insoluble species such as  $\text{Al}(\text{OH})_3$ , facilitating absorption (Yokel, 1997). Furthermore, bioavailability can be influenced by other factors, such as variable amounts of essential and nonessential trace minerals, metal binding ligands and other dietary constituents, that can enhance or inhibit Al absorption. It is well established that concurrent consumption of  $\text{Al}(\text{OH})_3$  with fruit juices or with some common organic constituents of the diet (citrate, ascorbate, lactate, succinate, etc.) can markedly increase the absorption of Al.

The main mechanism of absorption of Al is probably passive diffusion through paracellular pathways. Another proposed mechanism of absorption for Al is an energy-dependent process that involves calcium

channels. Al may be taken up into mucosal cells, which may provide a barrier to its absorption. Small amounts of Al may then be slowly released into circulation (Van der Voet, 1992). Free Al ions occur in very low concentrations, because they complex with many molecules in the body, such as organic acids, amino acids, nucleotides, phosphates, carbohydrates and macromolecules. Therefore, toxicokinetics and toxicodynamics of Al can vary depending on the nature of these complexes.

The mean plasma half-life of Al after intravenous administration in dogs is approximately 4.5h. From the circulation, Al distributes to every organ, and the highest concentration is found in the bone. Lungs have the highest concentrations after inhalation. Approximately 50% of the Al body burden is in the skeleton and 25% is in the lungs. Long-term oral exposure to Al results in an increase in Al levels in the bone and from there it is slowly released (Ahn *et al.*, 1995; Krewski *et al.*, 2007). Al also accumulates in the brain, kidneys, liver and in hematopoietic tissue. Slow elimination coupled with continued exposure may produce an increasing body burden of Al. Furthermore, Al levels increase with age, especially in the lungs. Within cells, Al accumulates in the lysosome, cell nucleus and chromatin. In the blood, about 80–90% of Al binds to plasma proteins (Wilhelm *et al.*, 1990). Evidence suggests that Al primarily binds to transferrin, and small amounts to albumin. It is important to note that binding of Al to albumin is nonspecific and much weaker than to transferrin.

In general, brain Al concentrations are lower than in many other tissues. Al is known to cross the blood–brain barrier (BBB) and enter the brain by transferrin receptor-mediated endocytosis. Following inhalation exposure, Al can enter the brain by two mechanisms: (1) via the olfactory tract and (2) via nasal epithelium and axonal transport (Perl and Good, 1987; Zatta *et al.*, 1993). It is noteworthy that the cells which accumulate the most Al are long-lived postmitotic cells, such as neurons (Ganrot, 1986). In rabbits, increases of four- to ten-fold and ten- to 20-fold Al concentrations in brain are associated with neurotoxicity and death, respectively. Al is actively removed from the brain by means of an energy-dependent process.

Regardless of the route of exposure, Al is primarily excreted from the circulation into the urine and very little in the bile. Renal elimination of Al depends upon the Al complex. For example, Al bound in a low-molecular-weight complex could be filtered at the renal glomeruli and excreted, while Al in a high-molecular-weight complex would not. Animal studies suggest that following a single exposure, Al levels in urine can elevate as much as 14-fold. Al is primarily excreted in the urine during the first 24h period, and returns to normal levels 5 days post-exposure (Ittel *et al.*, 1987). The rate of Al clearance is consistent with glomerular filtration rate (GFR), although proximal tubular Al reabsorption and

Al excretion in the distal nephron have been suggested. Several animal studies have revealed a decrease in Al clearance and an increase in  $t_{1/2}$  with increased Al concentration. This may be due to the high Al concentrations that probably formed unfilterable Al complexes, thereby reducing the plasma filterable Al fraction. Because of the limited GI tract absorption of Al, only a limited amount of Al excretes in the milk. Following oral ingestion, unabsorbed Al excretes in the feces. For further details on toxicokinetics and toxicodynamics of Al, readers are referred to [Krewski \*et al.\* \(2007\)](#).

## MECHANISM OF ACTION

The central nervous system (CNS) and skeletal system appear to be the two major target organs for Al toxicity. It has been known for a while that Al is involved in neurodegenerative diseases like Alzheimer's, encephalopathy and amyotrophic sclerosis ([Deloncle and Pages, 1997](#); [Savory \*et al.\*, 2006](#); [Krewski \*et al.\*, 2007](#); [Garcia \*et al.\*, 2010](#); [Bondy, 2010](#)). However, the exact mechanism by which Al induces neurotoxicity is yet to be elucidated. Al mainly deposits in the hippocampus, cortex and amygdala, which are the areas of brain that are also rich in glutamatergic neurons as well as in transferrin receptors. Upon entering the brain, Al displaces physiological cations, such as magnesium, calcium or iron, and modulates their metabolism. Studies suggest that Al neurotoxicity can be modulated by the levels of tissue and cytoplasmic calcium. Al, by replacing calcium in the synaptic area, perturbs neurotransmitter release and alters neurotransmitter systems. High Al levels appear to modify cholinergic neurotransmission. Al is known to associate with many epithelia and endothelia, including the BBB, and may be responsible for compromising the properties and integrity of these membranes ([Wen and Wisniewski, 1985](#); [Exley, 1996](#)). It has been demonstrated that in some conditions, Al can cross the BBB without altering the functional characteristics of the membranes, while in other conditions Al interacts with the BBB with subsequent effects upon its barrier function ([Vorbodt \*et al.\*, 1994](#)). Al-related toxicological effects are noticed on both sides of the BBB ([Deloncle and Pages, 1997](#)). In neurons, glutamic acid in the form of a stable Al–glutamate complex is unable to detoxify cellular ammonia, which leads to neuronal death ([Harris, 1992](#)). Important events such as accumulation of Al in lysosomes (protease-rich vacuoles) and the hyperphosphorylation of neurofilaments (NFs) are involved in the molecular mechanism of Al-induced neurotoxicity ([Bizzi and Gambetti, 1986](#); [Ganrot, 1986](#); [Delamarche, 1993](#)). Recent findings suggest that oxidative and nitrosative stresses are involved

as mechanisms in Al-induced toxicity ([Kim, 2003](#); [Satoh \*et al.\*, 2005](#); [Garcia \*et al.\*, 2010](#)).

Al competes with magnesium in the biological system despite an oxidation state difference, and binds to transferrin and citrate in the blood stream ([Ganrot, 1986](#); [McDonald and Martin, 1988](#)). Al may also affect second messenger systems and calcium availability ([Birchall and Chappell, 1988](#)), and irreversibly bind to cell nucleus components ([Crapper-McLachlan, 1989](#); [Dryssen \*et al.\*, 1987](#)). In addition, Al has been shown to inhibit neuronal microtubule formation.

## TOXICITY

Acute poisoning of Al in animals is rare, but a high acute dose or repeated long-term exposure can lead to serious toxicological effects. Toxicity of Al depends on its chemical form, route of exposure and animal species. Oral LD<sub>50</sub> values for Al nitrate in Sprague-Dawley rats and Swiss Webster mice are reported to be 261 and 286 mg Al/kg, respectively ([Llobet \*et al.\*, 1987](#)). For Al bromide, these values are 162 and 164 mg Al/kg, respectively. LD<sub>50</sub> values for Al chloride in Sprague-Dawley rats, Swiss Webster mice and male Dobra Voda mice are 370, 222 and 770 mg Al/kg, respectively ([Ondreicka \*et al.\*, 1966](#); [Llobet \*et al.\*, 1987](#)). The LD<sub>50</sub> value for Al sulfate in male Dobra Voda mice is reported to be 980 mg Al/kg. A single gavage exposure to 540 mg/kg as Al lactate was found to be lethal in female New Zealand rabbits ([Yokel and McNamara, 1985](#)). In subchronic and chronic studies, Al has been found to cause lethality in mice ([Golub \*et al.\*, 1987](#)), but not in rats ([Dixon \*et al.\*, 1979](#)) and dogs ([Pettersen \*et al.\*, 1990](#)). In dogs, the signs of Al toxicity may include dermatitis, coryza and nasal discharges, loss of black pigment on the nose pad, and aggressive and violent behavior.

Toxic effects of Al depend on the target organ. Such effects may in part be related to Al deposition and substitution of physiological elements, such as calcium, magnesium and iron. Alterations by Al deposits can occur in: (1) the bone, interfering in heme synthesis leading to anemia, (2) the myocardium, leading to myocardial infarction and (3) the brain, leading to neurotoxicity and cognitive impairment. In addition, Al can cause hepatic and renal dysfunction and osteoarthritis.

There is conclusive evidence that Al compounds are neurotoxic to laboratory animals following an oral exposure. Marked signs of neurotoxicity, including ataxia, splaying and dragging of hind limbs, and paralysis occurred in maternal mice that were exposed during gestation and lactation to Al with estimated doses of 184 mg Al/kg/day ([Golub \*et al.\*, 1987](#)) or 250 mg Al/kg/day ([Golub \*et al.\*, 1992](#)) as Al lactate. Adult mice

that consumed 195mg Al/kg/day as Al chloride for 5–7 weeks in a diet that also contained 3.5% sodium citrate showed neurotoxic effects (Oteiza *et al.*, 1993). The citrate is likely to have enhanced the responses of Al neurotoxicity. Changes in brain biogenic amines (decreased dopamine and 5-hydroxytryptamine, and increased norepinephrine) occurred in rats that were treated with 21.4mg Al/kg/day as Al nitrate by gavage for 6 weeks (Flora *et al.*, 1991). Recently, Bondy (2010) also reported that acute exposure to Al can cause clinical neurotoxicity.

Evidence suggests that more serious disturbances occur in the brain following Al exposure. An alteration of the blood–brain barrier (BBB) would be necessary for Al brain transfer, but the mechanism leading to this alteration is still completely unknown, even though Al-induced peroxidation is perhaps a process involved therein (DeLoncle and Pages, 1997). Elevated Al levels have been related to impaired motor function and to a number of cognitive deficiencies in both humans and experimental animals (Sturman and Wisniewski, 1988). Neurofibrillar degeneration has been observed in brain regions that exhibit elevated Al levels (Krishnan *et al.*, 1988).

Histopathologic changes in the brain of rats receiving 92mg Al/kg/day as Al chloride and a high level of Al citrate (598mg/kg/day) for 6 months, showed extensive vacuolization in the astrocytes, swelling of astrocytic processes, neuronal vacuolization and nuclear inclusions (Florence *et al.*, 1994). In other studies, increased Al levels and histological alterations in the brain (particularly increased numbers of abnormal and damaged neurons and reductions in cell density in areas of the hippocampus and neocortex) also occurred in rats that received an estimated 12mg Al/kg/day as Al fluoride in drinking water and base diet for 45–52 weeks (Varner *et al.*, 1993, 1998).

There is some evidence that neurotoxic agents given prenatally induce subtle neurobehavioral impairment and delayed development of nervous system functions without any morphological malformation (Vorhees *et al.*, 1979; Adams and Buelke-Sam, 1981). The entry of Al into the developing nervous system is enhanced by the immaturity of the BBB (Thomas *et al.*, 1989), and the increased neuronal expression of transferrin receptors (Mollgard *et al.*, 1987). Al crosses the placental barrier, accumulates in fetal tissues and produces embryo/fetal toxicity, birth defects and developmental and neurobehavioral toxicity. Reproductive and developmental effects of Al have been discussed in detail in the “Placental Toxicity” chapter of this book and elsewhere (Golub and Domingo, 1998; Garcia *et al.*, 2011).

It is important to mention that the acute toxicity associated with Al phosphide ingestion is primarily due to the formation of the highly toxic gas phosphine (PH<sub>3</sub>), instead of Al. There are incidences in which cows died by ingesting grains treated with Al phosphide that was used for fumigation.

Chronic exposure to Al results in an increase in Al levels in bones, and this may result in bone abnormalities including reduced bone formation and demineralization, or even osteoarthritis. Osteomalacia is observed in dogs and pigs exposed to Al. Chronic inhalation exposure to Al can cause pulmonary fibrosis. In addition, long-term exposure to Al can cause hepatic and renal failure, and endocrine disruption. There is no evidence that Al is carcinogenic.

## Diagnosis

Diagnosis of Al poisoning can be based on a history of Al exposure, clinical signs and confirmation of Al in animal tissues. Using an Atomic absorption spectrometer or an inductively coupled plasma, Al can be measured in tissue, blood, urine, feces and hair. Only urine measurement can indicate whether recent exposure to excess levels of Al has occurred. High concentrations in the lung usually reflect inhalation exposure and elevated levels in bone, liver and spleen reflect sequestration (Yokel, 1977). In the diagnostic setting, liver and kidney are tested for Al and stomach/rumen content for phosphine (PH<sub>3</sub>) when aluminum phosphide poisoning is suspected. Aluminum levels in the range of 6–11ppm in the liver and 4–5ppm in the kidney of cows and sheep are regarded as toxic levels. In dog liver, an Al level >1.2 ppm is considered high (Puls, 1994). Aluminum levels greater than 1200 ppm in the diet are considered toxic to cattle and sheep. Presently, there are insufficient data to relate aluminum exposure levels with blood or urine levels.

## TREATMENT

There is no specific antidote for acute Al toxicity. So, treatment relies upon symptomatic and supportive therapies. Use of activated charcoal and cathartics can be rewarding. In the case of Al phosphide, sodium bicarbonate (5% solution) can be administered to stop conversion of phosphide to phosphine gas. There is evidence that dietary Silicone (Si) can reduce gastrointestinal Al absorption and increase its elimination. Dietary Si can also reduce brain Al accumulations. In the case of chronic exposure to Al, chelation therapy with deferoxamine or 3-hydroxypyridine-4-ones is very effective.

## CONCLUSIONS

Aluminum is a commonly occurring metal in the environment, and as a result a small amount is normally present in the body. A single exposure or repeat exposure

to higher levels of Al or its compounds (particularly Al phosphide) often leads to serious toxic effects, including neurotoxicity or death. Chronic low-dose exposure can cause neurodegenerative damage involving multiple mechanisms. Since Al crosses the BBB and placental barrier, it produces neurotoxicity, and reproductive/developmental and neurobehavioral toxicity. There is no specific antidote for acute Al toxicity. Chelating agents such as deferoxamine and 3-hydroxypyridine-4-ones can be effective in reducing Al body burdens.

## ACKNOWLEDGMENTS

I would like to thank Mrs. Robin B. Doss, Ms. Michelle A. Lasher for their assistance in the preparation of this chapter.

# Arsenic

Tam Garland

## INTRODUCTION

The ubiquitous element arsenic (As) is a nonmetal or metalloid in group V of the period chart. Frequently it is referred to as arsenic metal and is classified for many toxicological purposes as a metal. It exists in several forms and has a long history of various uses. It has been used in preparations from insecticides to wood preservatives, herbicides and even has some medicinal uses. It is responsible for many poisonings in people, and animals, both large and small.

## BACKGROUND

Arsenic is a ubiquitous element with several different forms. The form may determine the toxicity. The prevalent valences are the +3 and the +5 form. Arsenic is found in both an organic form and an inorganic form with valence numbers ranging from +3 to +5. As<sup>+3</sup> or arsenite is more toxic than arsenate, or As<sup>+5</sup>. The toxicity of arsenic is determined by its form (Vahter, 1993).

It is found as different ores and rocks, which are mined, then smelted resulting in elemental arsenic and arsenic trioxide. In the environment, arsenic usually exists as the pentavalent form and soil microorganisms may methylate it. Since it is ubiquitous in many forms it is not likely that complete avoidance is possible.

Arsenic's sources and uses have a long and varied history. A partial list is available in Table 31.1.

## PHARMACOKINETICS/ TOXICOKINETICS

Different toxic disease syndromes are caused by the different forms of arsenic. Inorganic arsenicals and trivalent organics cause a disease syndromes characterized by an effect on the gastrointestinal (GI) tract and the capillaries. In extremely low doses it is possible that the body will develop a tolerance to the arsenic. Pentavalent organic arsenicals produce a neurological syndrome.

There are many factors influencing the absorption of arsenicals. Among those variables are the form of the metal, the particle size, the purity, the solubility, the species affected and the physical condition of the animal exposed. Susceptibility to inorganic arsenicals varies among species, being highest in humans, followed by dogs, rats and mice (Harrison *et al.*, 1958, Hays, 1982). So clearly there are many variables affecting the absorption and toxicity of this metal, which increases the difficulty of making accurate predictions of lethal amounts.

Pentavalent organic arsenicals are better absorbed than are the trivalent arsenicals, especially through the GI tract. Small amounts of either form may be absorbed via the intact skin, but it usually remains locally within the skin. However, absorption is limited by the size of the arsenical particle size. If the particle size is too large, it is not absorbed. Hence, a more toxic arsenical that is not absorbed because of large particle size may effectively be less toxic.

Once arsenicals are absorbed, the distribution is through the blood to all the organs of the body. Arsenic

TABLE 31.1 Sources and uses of arsenic

Sources	Valence/form	Uses
Commercial uses and products	Inorganic arsenic trioxide (+3) Inorganic sodium arsenite (+3) Inorganic copper acetoarsenite (+3) Inorganic arsenic trioxide (+3) Inorganic sodium arsenate (+5) Inorganic chromated copper arsenate (+5) Inorganic lead arsenate (+5) Organic pentavalent (+5)	insecticide, cattle dip (0.18%) defoliant (highly toxic) Paris green – insecticide (emerald green) smelters herbicide wood preservative insecticide and medicinal monosodium methylarsenate (MSMA) and disodium methylarsenate (DSMA) (highly toxic to cattle) ant bait leaded gasoline
Natural sources		ores, minerals, volcanoes ground water and soil
Medicinals	Potassium arsenite (+3) Organic trivalent arsenical Organic pentavalent arsenical Organic trivalent arsenical Organic pentavalent arsenical	Fowler's solution tonic/conditioner thiacetarsamide – heartworm treatment in dogs tryparsamide – trypanosomiasis – old melarsoprol – trypanocidal arsenical feed additives (arsanilic acid, sodium arsanilate, 3-nitro, 4-hydroxyphenylarsonic acid)

accumulates in the liver and is slowly distributed to the other tissues. The spleen, kidneys and lungs are able to accumulate large amounts of arsenic. Arsenic has been shown to cross into the placental barrier, particularly in monkeys, hamsters and gerbils (Flora *et al.*, 2011). Chronic doses are stored in the bone, the skin, and other keratinized tissues, such as skin, hair, hooves and nails (Agency for Toxic Substances and Disease Registry, 2007).

The biotransformation of the arsenicals is poorly understood. There is some conversion from the +5 state to the +3 state, but the redox equilibrium favors the +3.

Methylation occurs by microorganism in the soil, but inorganic arsenicals are also methylated *in vivo*. The *in vivo* process may aid in the detoxification process. The kidneys may reduce a small amount of pentavalent arsenic to the more toxic trivalent form.

Arsenicals are excreted through many processes. In most species, between 40 and 70% of the absorbed amount of pentavalent arsenicals are excreted through the urine within 48 hours (Vahter, 1983). It may also be excreted in much smaller quantities through the sweat. Trivalent forms of arsenic are excreted more slowly and through the bile into the feces.

## MECHANISM OF ACTION

Arsenite (+3) reacts with sulfhydryl groups (–SH) of proteins and inhibits the enzymes by blocking the active groups. The arsenite inhibits alpha-keto oxidases which

contain dithiol groups and are involved in oxidation of pyruvate. Lipoic acid, an essential co-enzyme for pyruvic acid oxidase, and alpha-oxyglutaric acid oxidase are inhibited by the arsenite. These play an essential role in the tricarboxylic acid cycle. Actively dividing cells that have a high oxidative energy requirement are most susceptible to the effects of arsenicals.

Arsenites induce vasodilation and can cause capillary damage. The cellular integrity of the capillary is affected by an unknown mechanism. Evidence of vascular instability is seen by the presence of congestion, edema and hemorrhage in most of the visceral organs of animals with acute poisoning. This same mechanism of action occurs with inorganic arsenicals and with organic trivalent arsenicals, and they may be considered as “vascular poisons” (Hann and McHugo, 1960; Jubb and Huxtable, 1993; Agency for Toxic Substances and Disease Registry, 2007).

Arsenates (+5) are a little different. They are uncouplers of oxidative phosphorylation. The inorganic pentavalents may substitute phosphate in this reaction. The result is an increase in body temperature. Organic pentavalents have an unknown mechanism of action. There is some thought that they may interfere with vitamins B<sub>6</sub> and B<sub>12</sub>, which may allow for the demyelination and subsequent axonal degeneration that occurs.

Although arsenicals have been classified as carcinogens in people, this has not been the case in animals. Experimentally there have attempts to document arsenic-related cancer in animals but the experiments have been unsuccessful (Chan and Huff, 1997; Agency for Toxic Substances and Disease Registry, 2007; Hughes *et al.*, 2011).

## TOXICITY

Inorganic arsenicals are up to ten times more toxic than pentavalent arsenicals. The order of toxicity from greatest to least follows this schematic: inorganic  $\text{As}^{+3}$  (arsenite) > inorganic  $\text{As}^{+5}$  (arsenate) > trivalent organics > pentavalent organics ( $\text{I As}^{+3} > \text{I As}^{+5} > \text{O As}^{+3} > \text{O As}^{+5}$ ). In other metal toxicities, the organics are more toxic but with arsenicals the inorganics are the more toxic.

Toxicity is also influenced by many factors, including particle size. The more finely ground, the more surface area there is for reactions. Solutions, such as dips and defoliants, are the most dangerous. However, the causes of the poisonings are varied. Debilitated animals are more sensitive. Since arsenic is not biodegradable, the soil and the old corrals around old dipping vats are still sources for arsenic poisoning. The area around smelters is also a source of poisoning, similar to that of dipping vats. Human mistakes and carelessness are the largest contributing factors to toxic events. For example, feeding a product known as gin trash instead of cotton seed hulls has resulted in numerous animals being poisoned.

Clinical signs caused by either inorganic or trivalent aliphatic arsenicals are similar. Peracute toxicities often result in sudden death within minutes to a few hours, if the dose is high, of dissolved arsenic ingestion. Acute poisonings have more clinical signs: abdominal pain or colic, vomiting, a staggering gait and weakness, clear incoordination, rapid weak pulse and shock, diarrhea, followed collapse and death. If the acute poisoning is through dermal contact, then the arsenic will also be systemic. The skin will have blisters, edema and may be cracked and bleeding, leaving the skin susceptible for secondary infection (National Academy of Science, 1977; Evinger and Blakemaore, 1984). Those receiving a lower dose over a period of time may have subacute poisonings and will likely live several days, developing depression and anorexia. Movements may be difficult, stiff and incoordinated. Diarrhea is dark and possibly hemorrhagic and very fluid. Hematuria may be present, or the urine may contain protein and casts (National Academy of Science, 1977; Osweiler *et al.*, 1985). However, those suffering chronic poisoning are easily fatigued and have dyspnea when they are moved. These animals display intense thirst and have a rough dry hair coat as well as dry, brick-red mucous membranes. Cattle are described as having enlarged joints.

Clinical signs of phenylarsenic poisoning occur within 3 days of a high dose or after chronic exposure. Most noticeable are the neurological signs. The animal is generally bright and alert but uncoordinated. The animal may or may not be blind and these animals may have erythema in the skin. Some of the neurological damage may be reversible unless the nerves are damaged.

Lesions are often dependent upon the dose and survival times. There may be no lesions at all in animals that die from peracute poisoning. However, even these animals have some GI irritation. With the exception of peracute deaths, most of the other animals that die from some form of arsenic poisoning may have excess fluid in the GI tract. In cattle there is hyperemia of the abomasum and this may be the only finding. If there are other lesions in cattle, it is often necrosis of the rumen mucosal epithelium. Ruminants have gelatinous serosal edema in the rumen, reticulum, omasum and abomasum. The GI tract may have indications of irritation and be hemorrhagic. Lesions are indicative of capillary damage and the liver is usually soft and yellow.

The phenylarsonics (+5) are used in feed additives and lesions would be expected to be associated with overdoses in the feed mixture. A "downer pig" may have severe abrasions with muscle atrophy. Microscopic lesions indicate there is demyelination in the optic nerve and the posterior cord.

## TREATMENT

A diagnosis of arsenic poisoning is important and is based upon clinical history and signs. If more than one animal is involved, then lesions may also be important. Diagnostic arsenic levels in the kidney and liver are usually more than 8 to 10 parts per million (ppm), unless several days have lapsed since exposure, in which case it would likely be 2–4 ppm. Diagnostic levels of arsenic in the urine and feces are greater between 10 and 20 ppm. Arsenic should not be found in phenylarsonic acid intoxications.

Arsenic can poison large and small animals. If small animals are not showing clinical signs then evacuation of the stomach followed by lavage with 1% of sodium bicarbonate solution is recommended treatment. As a general rule early treatment, within 4 hours of exposure, is best. In carnivorous small animals, emetics followed by gastric lavage is the best treatment. The lavage may be milk and egg whites or with 1–5 grams of sodium thiosulfate. In herbivores treatment within 4 hours of exposure is also best. A large saline purgative, demulcents, 20 to 30 grams of sodium thiosulfate orally followed by a 10% solution three times a day for the next several days are also effective.

For both carnivores and herbivores, if treatment is more than 4 hours after exposure, then dimercaprol (British anti-lewisite, BAL) at 1.5 to 5mg/kg, intramuscularly, two to four times a day for 10 days or until recovery should be administered. Treatment should also include sodium thiosulfate at 30–40mg/kg administered

intravenously two to four times daily until recovery, which should be within 2 to 4 days.

If the diagnosis is a phenyl arsenic compound, there is no effective treatment for nerve damage caused by these compounds. BAL is not effective for these intoxications.

Alternative experimental treatments include DMPS (2,3-dimercaptopropanesulfonic acid, Dimerval) and DMSA (2-3, dimercatosuccinic acid or succimer). DMPS has been shown experimentally to chelate arsenic in dogs when dosed at 3–5mg/kg in very slow infusion over 20 minutes or 4–8mg/kg orally every 6 hours. Arsenic intoxication has also been experimentally treated with DMSA or succimer in dogs at 7.5mg/kg every 6 hours.

## CONCLUSIONS

Determining the diagnosis and initiating treatment early will determine the prognosis. Acutely poisoned animals have a poor prognosis without early intervention. Understanding the differentials is important to institute the appropriate treatment for the appropriate condition. Arsenic produces signs of severe gastroenteritis, similar to those of pancreatitis, viral or bacterial gastroenteritis, irritating plants, caustic agents and zinc phosphide poisoning. Likewise, other heavy metals will produce similar clinical signs. However, poisoning with phenylarsonics, used most frequently in feed additives, has a high morbidity rate but is associated with a low mortality rate. Recovery generally requires 2 to 4 weeks.

# Cadmium

Stephen B. Hooser

## INTRODUCTION

Cadmium accumulation in plants and animals is increasing from several sources of environmental exposure. The application of rock phosphate (which contains varying amounts of cadmium depending on the source) and sewage sludge fertilizers results in cadmium deposition in the soil of pastures (Piscator, 1985; ATSDR, 2009). In addition to direct ingestion of soil containing cadmium, some forage plants extract cadmium from the soil. Although cadmium accumulation in the soft tissues of livestock has been demonstrated and there is ample experimental documentation of the toxicity of cadmium in animals, under natural conditions, documented cases of direct toxic or carcinogenic effects of cadmium in livestock have been uncommon (Dorn, 1979).

## BACKGROUND

Pure cadmium is a soft, silver-white metal with an atomic number of 48 and a molecular weight of 112.41. It is a divalent transition metal with chemical properties that are similar to zinc and is usually found as a mineral in combination with other elements to form cadmium oxide, cadmium chloride or cadmium sulfate (ATSDR, 2009). Numerous compounds are formed from cadmium and thus it is used in batteries, solders, semiconductors, solar cells, plastics stabilizers, and to plate iron and steel. All soil and rocks contain some cadmium. It can enter the environment from zinc smelting and refining, coal combustion, mine wastes, iron and steel production, and

from the use of rock phosphate and sewage sludge as fertilizers (Klasing, 2005).

Cadmium accumulation in plants and animals is increasing from a variety of sources, being the most severe in the vicinity of zinc smelters. The use of cadmium-containing mineral supplements in feed (e.g., from calcium phosphate), the application on pastures and hay fields of phosphate fertilizers (which contain varying amounts of cadmium depending on the source) and sewage sludge results in cadmium deposition in the soil (Piscator, 1985). Some plants readily extract cadmium from the soil thereby making it available for consumption. For example, cadmium concentrations in clover grown in soil fertilized with high cadmium rock phosphate were significantly higher than the concentrations in clover grown in soils treated with low cadmium phosphate fertilizer (McLaughlin *et al.*, 1997). A New Zealand national survey of soils and plants, and random testing of kidneys from grazing animals, revealed that there was an approximately two-fold increase in soil cadmium, while over a 3-year period, 14–20% of cattle kidneys exceeded the New Zealand maximum residue level of 1 µgCd/g (Roberts *et al.*, 1994). In a study where cattle were allowed to graze pastures treated with anaerobically digested sewage sludge for up to 8 years, cadmium was the only metal to accumulate consistently in increased amounts in the tissues of the cattle (Fitzgerald *et al.*, 1985). It has been reported that cattle grazing on sewage sludge-treated pastures consumed significantly more (up to three times) cadmium than cattle on control pastures (Reddy and Dorn, 1985). In addition, a Swedish study has found a direct correlation between cadmium in feed and pig kidneys (Grawe *et al.*, 1997). A study reporting the analysis of Wisconsin dairy feeds for heavy metals

found that cadmium concentrations in complete dairy feed rations were the closest of the heavy metals to U.S. maximum acceptable concentrations, suggesting that cadmium has the greatest potential to exceed those maximum standards if the amounts of cadmium in feeds increase in the future (Li *et al.*, 2005). However, several studies have failed to demonstrate any adverse clinical manifestations related to increased cadmium concentrations in the animals examined. In one study, although cattle on pasture fertilized with sewage sludge consumed increased amounts of cadmium and had increased fecal excretion and kidney accumulation of cadmium (Reddy *et al.*, 1985), there were no adverse health effects noted in these cattle (Dorn *et al.*, 1985). Similarly, when corn silage or corn that was grown on sewage sludge fertilized fields were fed to sheep or pigs, respectively, significant increases in kidney cadmium concentrations were measured, but no other adverse treatment-related effects were noted (Lisk *et al.*, 1982; Telford *et al.*, 1982). Although cadmium is of concern in the environment, and cattle grazing on cadmium-contaminated pastures have increased tissue concentrations of cadmium, two additional studies conclude that accumulation of cadmium in the liver and kidneys of cattle may be a moderately effective screen for the entry of cadmium into the human food chain, as long as liver and especially kidneys are not consumed (Sharma and Street, 1980; Johnson *et al.*, 1981). It has been reported that regardless of the concentrations of cadmium fed to livestock, the amount in meat, milk and eggs is always lower than that in the diet that the animal was eating. Thus, foods derived from those products decrease human exposure (Klasing, 2005). This is fortunate as chronic cadmium poisoning has been documented in humans. In these cases, it has been associated with osteoporosis, renal lesions, tissue mineral imbalances and death. In addition, the Department of Health and Human Services has determined that cadmium and cadmium compounds may be reasonably anticipated to be carcinogens.

### PHARMACOKINETICS/ TOXICOKINETICS

In animals, cadmium exposure is primarily through oral ingestion. Compared to other divalent cations such as zinc and iron, intestinal absorption of cadmium is relatively low, ranging from approximately 1 to 5% in most species, with up to as much as 16% in cattle, dependent on the dose (Klasing, 2005). Interestingly, cadmium bound to metallothionein in foods of animal origin is absorbed less efficiently than cadmium salts and therefore may be less available for uptake (Groten *et al.*, 1990).

After absorption, cadmium is transported in the plasma bound to albumin and in lesser amounts to other serum proteins. It distributes throughout the body with the highest concentrations in the liver and kidneys, which account for approximately one-half of the total cadmium in the body. Muscle and bone do not accumulate high concentrations of cadmium. Blood cadmium concentrations are indicators of recent exposure while urine cadmium is a better indicator of the body burden. Cadmium is not transported well into milk or eggs, or across the placental barrier (Klasing, 2005). In pregnant and lactating livestock, the toxicokinetics of cadmium have been compared. In this study, the kinetics of cadmium were measured in lactating versus non-lactating ewes after a single intravenous or oral administration of cadmium chloride. The non-lactating ewes exhibited a low cadmium bioavailability (0.12–0.22%), a large steady-state volume of distribution ( $23.8 \pm 5.41$ /kg), and a low blood clearance ( $0.20 \pm 0.031$ /kg/day) with a mean residence time of  $113 \pm 28$  days. The lactating ewes had a higher bioavailability (0.33–1.7%), and the mean residence time was close to that of the non-lactating ewes despite a greater blood clearance ( $0.46 \pm 0.0131$ /kg/day) because the volume of distribution of cadmium in the body was larger. The cadmium clearance in milk remained low in the lactating ewes (Houpert *et al.*, 1997).

In the body, cadmium is excreted very slowly, with daily losses of approximately 0.009% of the total via the urine and approximately 0.007% in the feces via the bile. Cadmium–protein complexes are excreted in the kidneys and then resorbed from the filtrate in the proximal tubules. This area of the renal cortex accumulates cadmium and is susceptible to damage and necrosis. Depending on the species, the biological half-life of cadmium can vary from months to years, which results in cadmium accumulating in animals as they age (Klasing, 2005). For example, several studies have documented age-related increases in cadmium in the kidneys of horses (Elinder *et al.*, 1981a; Anke *et al.*, 1989).

In mammals and birds, cadmium accumulates in the liver and kidneys at concentrations of 0.1–2.0 and 1–10 mg/kg wet weight, respectively. It has been discovered that animals with long life spans, such as horses, can accumulate large amounts of cadmium in their organs, particularly in their kidneys. In samples of renal cortex from old horses, concentrations of up to 200 mg/kg have been reported (Elinder, 1992).

### MECHANISM OF ACTION

Experimentally, acute exposure to high doses of inorganic cadmium leads to its accumulation in many organs,

eliciting liver and in some cases testicular damage (Dixit *et al.*, 1975; Habeebu *et al.*, 1998; Klasing, 2005). Once inside the cell, free cadmium binds to protein sulfhydryl groups, disrupting the cellular redox cycle, depleting glutathione and eliciting intracellular oxidant damage. In addition, its similarity to other divalent cations such as calcium interferes with their normal functioning (Klasing, 2005). Cadmium ions can displace zinc and other divalent metals from their binding sites on metalloproteins. For example, in the testis, cadmium can interfere with zinc proteins, leading to widespread apoptosis and necrosis (Xu *et al.*, 1999). In the liver, acute cadmium toxicity results in widespread hepatocyte apoptosis, followed by varying degrees of necrosis depending on the dose (Habeebu *et al.*, 1998). This is related, in part, to the effects of resident liver macrophages (Kupffer cells) to potentiate and increase the initial liver damage caused by cadmium alone. This has been demonstrated in several systems in which inhibition of Kupffer cells significantly decreases liver damage caused by a toxic dose of cadmium (Sauer *et al.*, 1997a, b).

Cadmium readily binds to, and induces the production of, metallothionein, a cysteine-rich, metal-binding protein. Binding to metallothionein does not have a major effect on the uptake of cadmium, but is, in part, responsible for retention of cadmium within cells and its long half-life (greater than 10 years in humans). Metallothionein does this by decreasing cadmium elimination, especially in bile. Within hepatocytes, metallothionein binds to cadmium, decreasing its hepatotoxicity. Experimentally, rats that have greater induction of metallothionein in the liver are somewhat protected from cadmium hepatotoxicity (Kuester *et al.*, 2002). However, in the kidneys the cadmium-metallothionein complex is nephrotoxic and it has been theorized that it may play a role in chronic poisoning in humans (Klaassen and Liu, 1997).

## TOXICITY

Increased exposure to cadmium in combination with zinc, lead and/or other metals continues to occur in the vicinity of non-ferrous metal smelters and processing facilities. These exposures have resulted in toxicoses, although it can be difficult to separate the effects of cadmium from those of lead, zinc and other metals. In one such case in the Netherlands, kidney cadmium concentrations were found to be twice those of cattle in control areas. However, although hemoglobin, blood iron concentrations and iron-binding capacity were lower in the cadmium-exposed cattle compared to controls, no adverse clinical effects were observed (Wentink *et al.*, 1992).

In an additional study in the Netherlands, bulls fed diets containing increased concentrations of cadmium, lead, mercury and arsenic had increased concentrations of cadmium in the kidney and liver, but did not exhibit histological lesions related to the intake of heavy metals (Vreman *et al.*, 1988). However, more recently, deaths in horses exposed to cadmium, lead and zinc from a non-ferrous metal processing plant in Eastern Europe were attributed to ingestion of these metals in their feed. Analysis of tissues from a number of these horses revealed extremely high concentrations of cadmium (40–100 times normal) and 3–6 times the normal concentrations of lead (Bianu and Nica, 2004). Toxicoses have also been reported in sheep and horses in the vicinity of non-ferrous metal smelters in China. Analysis of the tissues from these animals revealed lead and cadmium concentrations significantly higher than those of controls (Liu, 2003).

A survey of cadmium concentrations in tissues from healthy swine, cattle, dogs and horses in the midwestern United States was conducted in the mid-1970s. While the median cadmium concentration was low, at or below 0.6 ppm in the kidneys of cattle, swine and dogs, the median concentration in the kidneys was four times greater in horses (Penumarthi *et al.*, 1980). One study has indicated that horses may be more at risk for cadmium toxicity than other species. In this Swedish study, the cadmium concentrations in the kidney cortices of 69 otherwise normal horses were measured and correlated to any histological lesions that were noted. In that study, renal cadmium concentrations ranged from 11 to 186 µgCd/g wet weight, with an average of 60 µgCd/g. This study found a correlation between increased chronic interstitial nephritis and increasing cadmium concentrations in the renal cortex. There was no obvious relationship between the age and the frequency of renal lesions (Elinder *et al.*, 1981a). These same authors also found that cadmium concentrations in the kidney cortices were approximately 15 times greater than those in the liver of the same animals (Elinder *et al.*, 1981b). Age-dependent increases in kidney metallothionein and cadmium have also been reported in horses (Elinder *et al.*, 1981a; Jeffrey *et al.*, 1989; Plumlee *et al.*, 1996). However, these later studies and others (Holterman *et al.*, 1984) have not reported renal lesions similar to those reported by Elinder *et al.* (1981a). One diagnostic investigation has reported lameness and swollen joints, i.e., lesions of osteochondrosis, in addition to osteoporosis and nephrocalcinosis in horses near a zinc smelter in Pennsylvania. In the horses examined, kidney zinc and cadmium concentrations were elevated. In this case, it was postulated that the osteoporosis that was observed in one foal and the nephrocalcinosis seen in the foal and its dam were related to the elevated renal cadmium (Gunson *et al.*, 1982). When ponies were raised near a similar zinc smelter for periods of time up to 18.5 months, there were significant elevations in tissue zinc and cadmium concentrations.

Increases in tissue cadmium concentrations were correlated with increasing age, although increases in tissue zinc concentrations were not. Generalized osteochondrosis was present in joints of the limbs and cervical vertebrae, and there was lymphoid hyperplasia. From this study, it was concluded that the development of osteochondrosis was associated with increased exposure to zinc and possibly cadmium. However, other lesions of cadmium toxicosis, such as renal damage or osteomalacia, were not present (Kowalczyk *et al.*, 1986).

In wildlife, white-tailed deer (*Odocoileus virginianus*) harvested within 20 km of zinc smelters in Pennsylvania had very high kidney concentrations of cadmium and zinc. These deer were also reported to have had joint lesions similar to zinc-poisoned horses from the same area (Sileo and Beyer, 1985).

In humans, occupational exposure to cadmium has been associated with renal dysfunction and osteomalacia with osteoporosis. One of the earliest effects of chronic cadmium exposure is renal tubular damage with proteinuria (Bernard *et al.*, 1992). Other chronic effects can include liver damage, emphysema (through inhalation), osteomalacia, neurological impairment, testicular, pancreatic and adrenal damage, and anemia. Reproductive, developmental and tumorigenic effects have been reported in experimental animals (Lee and White, 1980; Thompson and Bannigan, 2008; Siu *et al.*, 2009; Flora *et al.*, 2011). Historically in the 1940s, high environmental exposure in one area of Japan from eating cadmium-contaminated rice resulted in itai-itai (ouch-ouch) disease. This was manifested by intense bone pains and pathological bone fractures, mainly in elderly women, with osteoporosis and renal dysfunction (Kobayashi, 1978). In addition, studies in Europe and China have demonstrated that low to moderate exposure to cadmium from zinc smelters resulted in a decrease in bone density, and an increase in fractures in women. In one of these studies, cadmium concentrations in the blood and urine were taken as biomarkers of exposure (Katzantzis, 2004). Experimental studies in animals have confirmed the adverse effects of cadmium on bones. Six mechanisms have been theorized to explain these effects: (1) interference with parathyroid hormone stimulation of vitamin D production in the kidney, (2) reduced renal vitamin D activation, (3) increased urinary excretion of calcium, (4) reduced intestinal calcium absorption, (5) interference with calcium deposition in bones and (6) interference with bone collagen production (Kjellstrom, 1992).

## TREATMENT

In animals, cadmium toxicosis is prevented by minimizing exposure in the environment and in feedstuffs.

## CONCLUDING REMARKS/FUTURE DIRECTIONS

Although toxicoses in domestic animals are uncommon, exposure is gradually increasing especially in grazing animals. Since chronic cadmium toxicity is of concern to humans, continued close observation and analysis of cadmium in animals is indicated to provide a system for environmental cadmium surveillance.

## Chromium, iodine and phosphorus

Larry J. Thompson

### CHROMIUM

Chromium is a metallic element that can exist in six valence states, with the trivalent chromium form most commonly found in nature as ferrochromite ores. Both trivalent and hexavalent (+6) are widely used in various industrial and manufacturing processes. Chromium is an essential trace element and functions in a number of metabolic processes including glucose, lipid and amino acid metabolism. Hexavalent chromium is considered to be more toxic than the trivalent form which may be a direct result of its increased systemic availability.

While hexavalent chromium is considered to be a human carcinogen, acute chromium toxicosis in animals is probably of minimum concern in all but the most unusual circumstances. Both hexavalent chromium and dichromate are easily converted to trivalent chromium in mammalian systems but the burning of chromium-treated lumber does not produce enough heat to convert the dichromate to the trivalent chromium form. Oil field contamination with hexavalent chromium has been associated with cases of cattle death (Thompson *et al.*, 1991) and a solution of strong, oxidizing chromium was responsible for dairy cattle deaths when the solution dripped on cattle and was absorbed dermally (Talcott *et al.*, 2005). Acute chromium toxicosis is associated with severe congestion and inflammation of the digestive tract, kidney damage and liver damage. Chronic toxicosis has been associated with gastroenteritis and dermatitis.

several common other forms including iodide ( $I^{-1}$ ) and iodate ( $IO^{-3}$ ). Iodine is widely distributed in nature in both organic and inorganic forms but only in low concentrations. Iodine is essential for the normal synthesis of thyroid hormones and a deficiency of iodine can result in thyroid enlargement or goiter. Deficiencies may occur from eating feeds grown on iodine-deficient soils or from the presence of goitrogenic substances (NRC, 2005a). High dietary iodine for a prolonged period of time can reduce the iodine uptake by the thyroid, causing the clinical syndrome of iodine deficiency.

Common dietary sources of iodine include iodized salt, ethylenediamine dihydroiodide (EDDI) and calcium iodate. Iodized salt can contain 0.01% iodine (100 ppm) and has not been associated with excess iodine exposure. EDDI has been used to prevent and treat foot rot in cattle, although its efficacy is unclear (Morgan, 2004). Toxic effects of iodine excess have been reported in cattle consuming iodine-containing feed additives (Thompson *et al.*, 1991). Clinical signs include decreased feed intake, decreased milk production, rapid breathing, nasal and ocular discharge, dry hair coat and non-responsive hock lesions. Affected cattle were on high intakes of iodine (68–600 mg/head/day and above) for several weeks before obvious clinical signs appeared. Young calves exhibited chronic coughing and profuse nasal discharge at 100–200 ppm dietary iodine. Removal of the excess iodine from the diet and supportive care usually results in rapid return to normal.

### IODINE

Iodine is a non-metallic element of the halogen group that occurs as a purple-black crystalline solid but has

### PHOSPHORUS

Most phosphorus in nature exists in combination with oxygen in the form of phosphates, primarily in igneous

and sedimentary rocks. Inorganic phosphates are commonly used as chemical fertilizers, food and feed supplements and have many industrial uses. Phosphorus is abundant in the animal body primarily as a structural component of crystalline hydroxyapatite in bone and teeth but also as required components of phospholipids, nucleic acids, nucleotides and enzyme cofactors. Phosphate ions also function in acid–base balance and other essential body functions. Phosphorus is an essential macroelement in nutrition and is an important consideration in the formulation of animal diets. The largest dietary source of phosphate will be in the form of inorganic phosphate supplements and other dietary sources may include plant-origin feeds as well as bone, meat, poultry and fish meals. Normal phosphorus nutrition and metabolism requires adequate calcium in the diet with an appropriate calcium-to-phosphorus ratio (Ca:P). While adverse effects of excess phosphorus are rare, they can occur with either excess dietary phosphates or deficient dietary calcium. If the Ca:P ratio is balanced, usually no wider than 2:1, animals can tolerate a wide range of dietary phosphorus levels (NRC, 2005b).

Excess phosphorus in the diet of ruminants, especially sheep, can result in the formation of urinary calculi in the kidney or bladder. This formation of stones can obstruct or completely block urine flow, especially in males, resulting in the bladder filling with urine and eventually rupturing into the abdominal cavity causing death. The problem can be prevented by correctly balancing calcium and phosphorus in the diet. Excess phosphorus in the diet of horses has resulted in nutritional secondary hyperparathyroidism, a condition usually associated with a high grain diet without appropriate calcium supplementation. The high dietary phosphate will depress the intestinal absorption of calcium with a decrease in plasma calcium and an increase in plasma phosphate levels. Low plasma calcium will stimulate the secretion of parathyroid hormone which will

increase bone mineral resorption activity. The skeletal bones will lose calcium and the demineralized bone will be replaced by fibrous connective tissue with the facial bones often becoming enlarged (Joyce *et al.*, 1971), leading to the common term of big head disease in horses. It is also known as bran disease, since feeding high dietary levels of bran, which is high in phosphate and low in calcium, has historically been a cause of the disease. In all animals, optimum animal performance will be closely associated with optimum dietary calcium and phosphorus balance.

Phosphorus, in the form of white or yellow phosphorus, has historically been used as a rodenticide but is uncommon today. Initial clinical signs following ingestion would include gastroenteritis with vomiting and diarrhea. If the animal survived several days it would often develop a secondary phase of severe liver damage with renal insult also occurring.

# Copper

Larry J. Thompson

## INTRODUCTION

Copper is a transition group metal with high electrical and thermal conductivity. The chemical abbreviation for copper is Cu, which comes from the Latin word *cuprum*, which refers to the island of Cyprus, known in the ancient times for large deposits of copper ore. The Bronze Age followed the discovery that adding tin (and other metals) to copper made the resulting metal alloy much more durable. Copper has been shown to be an essential element for both animals and plants but can be toxic under certain conditions. This chapter describes the toxicity and deficiency of copper in animals.

## BACKGROUND

Toxic insults from copper occur in two main categories, acute and chronic. The acute overexposure of animals to copper can occur by both oral and parenteral routes (Galey *et al.*, 1991) but is relatively uncommon. Sheep are very susceptible to chronic copper poisoning, where even a slight excess of copper in the diet can build up over weeks or months to cause problems. Cattle and other ruminants are less likely to suffer from chronic mild to moderate copper excesses in the diet but can be affected by relatively high levels (Gummow, 1996). Monogastric animals seem to tolerate excess dietary copper much better than ruminants and high dietary copper additions (up to 250 ppm) have been used for

growth promotant effects, such as in pigs and poultry. Finally, certain breeds of dogs (e.g., Bedlington terriers) have a genetic predisposition for liver copper accumulation similar to Wilson's disease in humans (Taboada and Thompson, 1997). Each of these may have a different clinical presentation with the main target organs for acute copper exposure generally being the gastrointestinal tract, liver and kidney with the target organs for chronic problems being the liver, red blood cells and kidney.

Dietary sources of copper include normal plant concentrations of copper, with forages and cereal grains usually containing less than 10 ppm copper on a dry matter (DM) basis. Some oilseed meals can contain up to 35 ppm copper in DM. By far the largest source of copper in the diet will be feed additives such as copper sulfate, copper chloride and copper oxide. Additional sources of copper for the animal may be chelated copper sources in the diet or the administration of boluses containing copper metal wires or other solid forms of copper that remain in the rumen/reticulum and slowly dissolve over time. Misformulation of rations or errors in the mixing of feed can result in high concentrations of copper. Problems can arise from the use of feed formulated for a copper-tolerant species when used for a copper-sensitive species such as sheep, or the use of trace mineralized salt in sheep diets. Other sources for large acute oral copper exposures would include copper sulfate foot baths and copper algacides or fungicides. Most water sources have low copper concentrations but the use of copper piping with slightly acidic water can result in additional copper being dissolved.

## PHARMACOKINETICS

Copper is primarily absorbed in the small intestine and transported in the blood by transcuprein and albumin, which serve to reduce the oxidative effects of divalent copper. In the liver, copper can be stored in the lysosomes, excreted in the bile or incorporated into ceruloplasmin for use and transport to cells in other parts of the body. Biliary excretion is the major mechanism responsible for copper homeostasis and identified genetic disorders of copper accumulation are due to impaired biliary excretion. Copper is utilized by essentially every cell in the body and there are several important copper-dependent enzymes including cytochrome C oxidase, superoxide dismutase, lysyl oxidase and dopamine beta hydroxylase.

In the ruminant, copper has a complex interrelationship with dietary molybdenum and sulfur which, when present in excess, will both decrease copper absorption and inhibit copper utilization. In the reducing environment of the rumen, excess sulfur favors the formation of sulfides which can inhibit copper absorption from the gastrointestinal tract. Additionally, the formation of tri- and tetrathiomolybdates can also inhibit the absorption of copper or, if in high amounts, can cause systemic effects by holding copper in a non-biologically available form (NRC, 2005).

## MECHANISM OF ACTION

Acute exposure to excess copper causes gastrointestinal irritation and can cause erosions of the mucosa as well as a blue-green discoloration of the contents and wall. Normally, the free copper concentration in cells is kept very low by copper-binding proteins such as metallothionein, glutathione and copper chaperone proteins. An excess of copper can overwhelm these binding proteins and allow free copper ions to exist in the cell which can directly bind proteins and nucleic acids. Additionally, the free copper can form reactive oxygen species and hydroxyl radicals, causing lipid peroxidation of membranes and damage to nucleic acids and cellular proteins (NRC, 2005).

Chronic copper toxicosis in sheep is caused by the inability of the sheep to increase the biliary excretion of copper in response to dietary increases. Copper will then accumulate in the liver but during this accumulation phase there will be little or no evidence of negative effects (Bremner, 1998). If accumulation continues, the liver can suffer direct damage from the high concentrations of copper. When damage is severe, hepatic necrosis develops and copper is released into the bloodstream. Additionally, stress to the animal can also accentuate this mobilization of copper from the liver and into the

bloodstream. Increasing copper concentrations in the bloodstream will overwhelm the protective transport actions of transcuprein and albumin, which can then result in the lysis of red blood cells due to the oxidation of the red blood cell membrane by ionic copper. As copper is mobilized from the liver, it can accumulate in the kidney. The kidney can be damaged both from the accumulation of copper as well as the direct toxic effects of hemoglobin following the hemolytic event. Cattle can also be affected by chronic copper toxicosis, with a strong suspicion of breed differences (Du *et al.*, 1996) but with hemolysis occurring with less frequency than in sheep.

Chronic copper toxicosis in dogs is primarily seen in the Bedlington terrier where genetic studies have shown it to be an autosomal recessive disorder (Forman *et al.*, 2005). Other breeds including West Highland White terriers, Skye terriers and Doberman pinschers (Speeti *et al.*, 1998) have breed-related hepatic copper accumulation, the origin of which is less defined. Chronic copper toxicosis in dogs will also have a period of copper accumulation without clinical signs or detectable damage to the liver. As copper concentrations increase, the animal develops a chronic active hepatitis with necrosis and inflammation. As with sheep, excess free copper damages many cellular components of the liver, including the lipid peroxidation of mitochondrial membranes. A sudden release of copper with the resulting hemolytic crisis is much less likely to occur in dogs. The disease usually appears at 2–6 years of age, with animals often showing no problems before this time.

## TOXICITY

There is a paucity of information on the amount of copper needed for acute poisoning in various species, but the general range is given as 25–50 mg/kg of body weight. Copper sulfate is most often implicated in clinical cases as the copper source. The toxic dose of copper sulfate in cattle is 200–800 mg/kg, with sheep more sensitive at 20–100 mg/kg. Affected animals show clinical signs of salivation, gastroenteritis and abdominal pain which may rapidly develop to dehydration, shock and death. Animals that survive longer than 24–48 h develop liver and kidney damage and the animal may have an acute hemolytic crisis. Postmortem findings include gastroenteritis and a blue-green discoloration to the gastrointestinal tract and contents. Varying degrees of liver and kidney lesions are present, with milder lesions in acute deaths and more dramatic lesions developing after 48 h. Diagnostic testing of the intestinal tract contents shows a high level of copper. In acute deaths, there are normal levels of copper in the liver and kidney. If the

animal survives over 24h, elevated copper levels are found in liver and kidney.

In sheep, even normal levels of copper in feeds (10–20ppm) can cause hepatic copper accumulation when the molybdenum level in feed is low (less than 1ppm). As the copper-to-molybdenum ratio (Cu:Mo) increases above 6:1, the risk of copper accumulation increases, with those diets whose ratio is above 20:1 being very dangerous for sheep. At the higher Cu:Mo ratios, toxic accumulation of copper in the liver can occur over a matter of weeks. In affected animals, there may be an acute hemolytic crisis and the animals show clinical signs of weakness, anorexia, icterus, dyspnea and pale mucous membranes. There may be hemoglobinuria and death is common among severely affected animals. Postmortem findings include icterus, swollen liver, enlarged spleen and the kidneys appear dark, often referred to as gunmetal blue or black kidneys. Antemortem testing of serum copper often shows an elevation above normal, but this decreases over time with a rapid decrease following fluid therapy. Postmortem diagnostic testing for copper should be performed on both liver and kidney. Mobilization of copper from the liver may reduce copper concentrations to normal levels but the mobilized copper is then accumulated in the kidney. The ratio should be tested for both copper and molybdenum. The close environment of the sheep should be inspected for extraneous sources of copper.

Young dogs with genetic susceptibility to chronic copper toxicosis may develop an acute syndrome of weakness, vomiting and anorexia. Older dogs may present with a more chronic syndrome of weight loss and anorexia, which may progress to ascites and neurological signs related to a developing hepatic encephalopathy. If untreated, the animal may succumb to liver dysfunction and postmortem findings may include a cirrhotic liver. Antemortem diagnostics would include an evaluation of liver enzymes. In suspect cases, a liver biopsy should be used to confirm elevated copper content (Taboada and Thompson, 1997).

## TREATMENT

Treatment of animals acutely poisoned with copper mainly consists of supportive treatment directed at the shock, dehydration and damage to the gastrointestinal tract.

Treatment of sheep with severe clinical signs following hemolytic crisis is often unrewarding. Supportive care should include fluid therapy and the consideration of a blood transfusion. Ammonium or sodium molybdate (50–500mg) and sodium thiosulfate (0.3–1g) should be used daily as a drench for up to 3 weeks not only in affected animals but also in other animals that have received the same diet. Ammonium tetrathiomolybdate has been suggested as a treatment but is difficult to

obtain. It can be administered IV or SQ at 1.7–3.4mg/kg on alternate days for three treatments. Molybdenum in the diet can be increased to 5ppm and zinc can be supplemented at 100ppm to reduce copper absorption.

Dogs affected with chronic copper toxicosis should be fed a low copper diet, e.g., avoiding organ meats which are usually higher in copper. The use of oral chelating agents is suggested to enhance urinary excretion of copper. The use of d-penicillamine at 10–15mg/kg PO twice daily or the use of trientine hydrochloride at 10–15mg/kg PO twice daily have been suggested. Liver enzymes should be monitored every 6 months and consideration be given to liver biopsy to assess liver copper concentrations. The addition of elemental zinc to the diet (100–200mg/day as the acetate) should be considered to reduce copper absorption.

## CONCLUSION

In trace amounts, copper is an essential element, but in excess it is a toxicant. In general, sheep and certain breeds of dogs are more susceptible to copper poisoning. Copper produces toxicity by multiple mechanisms. Poisoned animals are usually treated with ammonium molybdate and sodium thiosulfate. In addition, supportive care including fluid therapy and blood transfusion are beneficial.

# Fluoride

Larry J. Thompson

## INTRODUCTION

Fluorine is a member of the halogen group on the periodic table and is rarely found in elemental form in nature but instead exists as fluoride, the monovalent anion, combined with other elements. The most common mineral containing fluoride is fluorspar, also known as fluorite ( $\text{CaF}_2$ ), and soils generally contain calcium fluoride ( $\text{CaF}_2$ ). Although now rare, sodium fluoride and sodium fluorosilicate ( $\text{Na}_2\text{SiF}_6$ ) had been used as insecticides and anthelmintics. Sodium fluoroacetate (compound 1080) is another formerly used rodenticide that is rarely seen in the United States today but may be found in other parts of the world (e.g., Australia). Fluoroacetate can also be found naturally in several species of plants (*Gastrolobium* spp., *Oxylobium* spp. and others). Sodium fluoride, sodium fluorosilicate and fluorosilicic acid have been used in the United States for the fluoridation of drinking water for humans to prevent the development of dental caries (CDC, 2001). When the gas hydrogen fluoride (HF) is dissolved in water it forms hydrofluoric acid, a very hazardous chemical that has industrial and laboratory uses such as purifying metals, etching glass and cleaning semiconductors due to its ability to dissolve silicates and metal oxides. This chapter will stress the chronic effects of fluoride excess, also called fluorosis or fluoride toxicosis, in large animals.

## BACKGROUND

Fluoride is present at low levels in virtually all feed and water sources, thus animals will have continuing

exposure throughout their lifetime. While a small amount of fluoride in the diet has been shown to improve bone and teeth development, a chronic excess of fluoride can have adverse effects on teeth, bone and other body systems. Large animals have been exposed to excess fluorides through the ingestion of high-fluoride rock phosphates used as nutritional supplements, by the ingestion of forages contaminated with excess fluorides from industrial pollutants or volcanic emissions, or through water containing excess fluorides from industrial pollution or dissolved from natural sources (Shupe and Olson, 1971, 1983). Rock phosphates destined for animal diets must be defluorinated before use or have a phosphorus to fluorine ratio (P:F) of more than 100:1 in order to avoid exposing the animal to excess fluoride (Osweiler, 2004). Following a long history of problems, industrial contamination of forages and water with excess fluoride has decreased due to recognition of the problems caused by excess fluoride and increased regulatory controls on fluoride-emitting industries. Historical point sources for fluoride emissions have included the smelting industries (e.g., aluminum, copper and steel), brick or ceramic product factories, coal-fired power plants and the phosphate-processing industries. Plant uptake of fluoride by translocation from the soil is usually not an important source of fluoride for grazing animals. Much more significant sources include airborne fluoride that settles on plant surfaces and fluoride from soil that is ingested directly or contaminates the plant (NRC, 2005). Acute fluoride poisoning in large animals is rare but can occur following exposure to fluoride-containing commercial products (Bischoff *et al.*, 1999) or to ash and tephra following volcanic eruptions (Shanks, 1997).

## PHARMACOKINETICS AND MECHANISM OF ACTION

Sodium fluoride is readily absorbed from the digestive tract and is several times more biologically available than fluoride compounds from feed or environmental sources. Fluoride is distributed to all parts of the body with approximately 50% of absorbed fluoride being excreted by the kidneys. The remainder will be incorporated into bone and teeth with very little accumulation in the soft tissue. Fluoride concentrations in the blood, urine and soft tissues may reflect recent ingestions but will also increase slowly over time with continuing excess fluoride exposure and accumulation in the bone. Greater than 95% of the body burden of fluoride will be contained in the bones with bone levels dependent upon the amount of fluoride ingested, duration of exposure, bioavailability, species, age and diet of the animal involved. If dietary fluoride exposure decreases, bone fluoride levels will decrease slowly over a long period of time. In cattle there appears to be a partial placental barrier to the movement of fluoride to the fetus as even high levels of fluoride in the diet of the dam did not adversely affect the health of the calves, even though higher fetal blood and bone fluoride concentrations resulted (NRC, 2005). Fluoride is excreted in the milk but this does not appear to be a significant source for the neonate.

The major adverse effects of chronic excess fluoride ingestion concern the teeth and bones of affected animals. Fluoride substitutes for hydroxyl groups in the hydroxyapatite of the bone matrix which alters the mineralization and crystal structure of the bone. Bone changes induced by excess fluoride ingestion, termed skeletal fluorosis or osteofluorosis, include the interference of the normal sequences of osteogenesis and bone remodeling with the resulting production of abnormal bone or the resorption of normal bone. The fluoride content of bone can increase over a period of time without other noticeable changes in the bone structure or function. Once lesions start to develop, they are usually bilateral and symmetric. The most consistent gross changes are abnormal bone formation on the periosteal surface with thickening of the cortex. In cattle, earliest clinical changes usually occur on the ribs and mandible as well as the medial surfaces of the metatarsal and metacarpal bones. Histologically, bones will have abnormal remodeling and mineralization with irregular collagenous fibers and excess osteoid tissues. While an excess of ingested fluorides can adversely affect the bones at any time in the animal's life, the bones in younger animals are more responsive to the excess fluoride.

Dental fluorosis develops when the period of excess fluoride intake occurs during the period of tooth development; in cattle this will generally be before 30–36

months of age. Teeth are affected during development with damage to ameloblasts and odontoblasts and the resulting abnormal matrix unable to mineralize normally (Shearer *et al.*, 1978). Both enamel and dentine are adversely affected. Affected teeth may erupt with mottling (alternating white opaque horizontal areas or striations in the enamel), hypoplasia, dysplasia (abnormal soft dull white chalky enamel or horizontal zones of constriction), erosion or pitting of enamel and affected teeth are prone to excessive abrasion and discoloration.

Acute fluoride toxicosis occurs when soluble forms of fluoride (e.g., sodium fluoride) are ingested in large doses. Absorption is rapid and clinical signs can appear within 30–60 min following ingestion. Although the exact mechanism of action is not known with certainty, fluoride concentrations in blood and soft tissues rapidly increase which leads to hypocalcemia. Sudden death from acute fluoride exposure is thought to involve the development of hyperkalemia or diminished  $\text{Na}^+/\text{K}^+$ -ATPase activity and the inhibition of glycolysis (NRC, 2005). Fluoride can induce oxidative stress and modulate intracellular redox homeostasis, lipid peroxidation and protein carbonyl content. Fluoride is thought to inhibit the activity of antioxidant enzymes, such as superoxide dismutase, glutathione peroxidase and catalase. Depletion of glutathione results in excessive production of reactive oxygen species (ROS) at the mitochondrial level, leading to the damage of cellular components. Fluoride can also alter gene expression and cause apoptosis (Barbier *et al.*, 2010). Genes modulated by fluoride include those related to the stress response, metabolic enzymes, the cell cycle, cell–cell communication and signal transduction.

## TOXICITY

There are a number of factors that influence the amount of fluoride required to produce specific lesions and clinical signs including the amount of fluoride ingested, duration of exposure, bioavailability, species, age and diet of the animal involved. The point where fluoride ingestion becomes detrimental to the animal also varies from animal to animal. Clinical signs develop slowly and can be confused with other chronic problems. Animals often show non-specific intermittent stiffness and lameness, which appear to be associated with periosteal overgrowth leading to spurring and bridging near joints as well as ossification of ligaments, tendon sheaths and tendons. The clinical presentation may easily be confused with other conditions, such as degenerative arthritis, but the lesions associated with fluorosis are not primarily associated with articular surfaces. In severe cases,

affected cattle may become progressively lammer and eventually may refuse to stand or may stand with rear legs upright and be on their knees to graze (Shupe and Olson, 1983). Lameness in cattle leads to abnormal hoof wear with elongated toes, especially in the rear legs. In long-term studies with cattle on varying levels of fluoride intake, skeletal neoplasms were not seen even in cattle with severe osteofluoritic lesions (Shupe *et al.*, 1992).

A great deal of effort has gone into the classification of dental lesions in cattle produced by excess fluoride ingestion. The incisor teeth are evaluated for enamel defects and abrasion pattern. The usual classification system ranges from a value of 0 for normal teeth to a value of 5 for severe fluoride effects (Shearer *et al.*, 1978; Shupe *et al.*, 1992). Because of the nature and complexity of the disease these dental lesion should not be the sole criterion for diagnosis. In general, severely affected teeth appear with brown or black discoloration, may have enamel defects and show increased wear including exposure of the pulp cavity, which causes pain while chewing roughage or swallowing extremely cold water. There will be a correlation between lesions on incisor teeth and those cheek teeth that form and mineralize at the same time. Cheek teeth that are abnormally worn cause improper mastication with roughage being difficult for the animal to utilize. The animal will have variable and decreased intake and the decreased production, slowed growth and general poor health associated with poor nutritional status. Animals with chronic exposure to excess fluorides have dry skin and hair coat.

Acute fluoride poisoning of cattle can result in clinical signs of depression, weakness and ataxia with postmortem findings of gastroenteritis (Bischoff *et al.*, 1999) and degenerative changes in the renal tubular epithelium.

## TREATMENT

Diagnosis of chronic fluoride toxicosis is based upon clinical signs, exposure history, dental lesions, evaluation of lameness and bony lesions and elevated urinary fluoride concentrations. Normal cattle urine contains less than 6 ppm fluoride. Animals having recent exposure or continuing release from fluorotic bone will have 15–20 ppm urinary fluoride (Oswailer, 2004). The biopsy of a rib or coccygeal vertebrae for fluoride analysis, as well as radiographic examination of teeth or bones, may also be helpful. A full postmortem examination should be performed, with attention to bone and teeth for both gross and histopathologic examination. Various bone samples should be submitted for fluoride analysis including metatarsal, metacarpal, rib, pelvis and mandible. Normal values for cattle are 400–1200 ppm fluoride

on a dry, fat-free basis. Animals affected with chronic fluorosis can contain 3000–5000 ppm fluoride on a dry, fat-free basis. Analysis of feed, water or suspect material should also be included.

There is no specific antidote or treatment for chronic fluoride toxicosis. Sources of excess fluoride should be identified and removed from the diet. With reduction of dietary fluoride to background levels, mild to moderate bone changes may be reduced and normal bone laid down. Extensive bone lesions will not be remodeled to normal and teeth lesions are irreversible. Symptomatic and supportive care for animals with bone and teeth changes include providing high-quality easily masticated feeds, limited grazing area and provisions to avoid cold or frozen water. For mild fluorotic changes, improving the diet and grazing may avoid excess wear on the teeth and reduce mastication problems.

## CONCLUDING REMARKS

Animals can be intoxicated with fluoride from its higher concentrations in supplemented feed or drinking water. The level of fluoride contamination in drinking water is dependent on the nature of the rocks and the occurrence of fluoride-bearing minerals in ground water. While in small amounts fluoride is necessary for teeth and bone development, in higher concentrations fluoride is toxic. Fluoride causes toxicity through multiple mechanisms. In addition to inhibition of  $\text{Na}^+/\text{K}^+$ -ATPase, fluoride can induce oxidative stress and modulate intracellular redox homeostasis, lipid peroxidation and protein carbonyl content, as well as alter gene expression and cause apoptosis. A chronic excess to fluoride can have adverse effects on teeth, bones and other body systems. Diagnosis is based on analysis of feed, water and bones. There is no specific treatment for fluoride toxicosis.

# Iron

Stephen B. Hooser

## INTRODUCTION

Iron is an essential element necessary for animal and plant life. It works as an oxygen (O<sub>2</sub>) carrier in hemoglobin/myoglobin and is involved in numerous biological oxidation–reduction reactions, including photosynthesis. Iron is present in cytochrome P450 and is crucial for the metabolism of many chemicals in the liver, kidney and other organs. Deficiencies in iron can result in anemia. Excess iron can cause iron overload and organ damage, while oxidation of ferrous to ferric iron in hemoglobin results in methemoglobinemia and an inability of red blood cells (RBCs) to carry O<sub>2</sub>. Consequently, because of its importance, the uptake, distribution, storage and excretion of iron is very tightly regulated in animals under normal conditions. Because of its reactivity, free iron compounds are sequestered with proteins to ensure that they do not initiate intracellular oxidative damage through electron donation and the formation of reactive oxygen species (ROS) such as hydroxyl radical. In this chapter, we will deal primarily with clinical animal exposures to excess iron through ingestion, parenteral administration or genetic iron storage abnormalities. Nutritional deficiencies or exposure to chemicals causing methemoglobin formation such as nitrates in ruminants, or nitrites and chlorates in all species, are discussed elsewhere.

## BACKGROUND

Iron is very abundant in the universe and is the fourth most abundant element on earth. Its atomic number is 26

and its atomic weight is 55.847. It has been recognized to be an essential nutrient for more than 100 years and is present in all the cells of the body. The largest amount of iron is incorporated into the proteins, hemoglobin and myoglobin. Within RBCs (erythrocytes), hemoglobin transports O<sub>2</sub> from the lungs to cells throughout the body, while myoglobin binds O<sub>2</sub> for use in muscle cells (Klasing, 2005). Iron present in the serum is bound to the protein transferrin, and in milk is bound to lactoferrin. Iron-containing proteins in the mitochondrial electron transport chain are essential for oxidative phosphorylation and energy production. Iron is also contained in enzymes of the Krebs cycle and in cytochromes P450 which are necessary for the metabolism of chemicals (Fairbanks, 1994).

The iron content of feedstuffs can be highly variable depending on the components. Iron in plants is subject to wide variation depending on the type of plant and the amount of iron in the soil, while many animal-based feed components are often rich in usable iron. The iron content of water can also vary greatly (Klasing, 2005). Large amounts of iron in water give the water a rusty color and a metallic taste, but upper limits of iron in drinking water for livestock and poultry have not been established since experimental data are not sufficient to make definite recommendations (NRC, 1974).

Worldwide, iron-deficiency anemias affect large numbers of people, but nutritional iron deficiencies are much less of a problem in animals. However, there are groups of animals which are vulnerable to iron deficiency including newborn piglets, veal calves and those animals with parasitic infestations (Underwood, 1977). For instance, newborn piglets have very low concentrations of liver iron (29mg/kg) compared to newborn rabbits whose liver iron stores average 135mg/kg.

There is accumulating experimental evidence in laboratory animals that excessive iron deposits in the brain, and alterations in iron metabolism, play an important role in neurodegenerative diseases (Connor *et al.*, 1995; Lan and Jiang, 1997; Fredriksson *et al.*, 1999; Dal-Pizzol *et al.*, 2001; Qian and Shen, 2001; Arosio and Levi, 2002; Jomova *et al.*, 2010).

## PHARMACOKINETICS/ TOXICOKINETICS

The homeostatic regulation of iron in the body is complex and involves uptake, transport, utilization, storage and loss. Under normal conditions, iron is poorly absorbed from most diets with approximately 5–15% absorbed from the gastrointestinal (GI) tract. This uptake can double in iron deficiency. The body has a very limited ability to excrete iron, therefore iron homeostasis is maintained by adjusting iron absorption to the body's needs. The amount of dietary iron that is absorbed through the GI tract is determined by the needs of the individual animal and is inversely related to serum ferritin concentrations (Bothwell *et al.*, 1979). There are four main factors influencing iron absorption in the GI tract: (1) individual factors including the animal's age, iron status, and health, (2) conditions in the GI tract, (3) the chemical form and amount of iron ingested and (4) other components of the diet which can enhance or reduce intestinal absorption. Iron is absorbed by enterocytes of the small intestine in ferrous ( $\text{Fe}^{2+}$ ) form and transferred to the serum where it is converted to the ferric ( $\text{Fe}^{3+}$ ) form and bound to transferrin (Goyer and Clarkson, 2001). In normal animals, the majority of fecal iron comes from ingested iron which is not absorbed. Once absorbed, the body vigorously retains ingested iron unless bleeding occurs with daily iron loss limited to about 0.01% (of the body total) per day (Goyer and Clarkson, 2001). It has been found that even in the face of hemolytic anemia with destruction of erythrocytes, less than 1% of the iron is excreted in the urine and feces (Underwood, 1977).

In the bloodstream, serum iron is primarily bound to transferrin with lesser amounts bound to ferritin. Iron in the serum forms a pool from which it enters, is transported, leaves and re-enters at a variable rate for the synthesis of hemoglobin, ferritin, cytochromes and other iron-containing proteins. Of the total iron in the body, approximately two-thirds is bound to hemoglobin and 10% to myoglobin and iron-containing enzymes, with the remainder bound to the storage proteins ferritin and hemosiderin (Goyer and Clarkson, 2001). Ferritin and hemosiderin are found throughout the body with the main concentrations being in the liver, spleen and bone marrow. They are protective in that they keep cellular

iron in a bound form. Ferritin contains up to 20% iron while hemosiderin is up to 35% iron. In the normal animal, non-viable RBCs are removed from the circulation by cells of the reticuloendothelial system in the liver, spleen and bone marrow. There, heme is broken down and the iron recycled for further use. In aged animals, when large amounts of iron are injected and rapidly cleared from the serum, or during chronic iron storage disease, the iron is preferentially deposited as hemosiderin thereby increasing intracellular concentrations and giving rise to the hemosiderosis that can be seen histologically (Underwood, 1977; Goyer and Clarkson, 2001).

## MECHANISM OF ACTION

For many functions, the body utilizes ferrous ( $\text{Fe}^{2+}$ ) iron to bind molecular  $\text{O}_2$ . In this way,  $\text{O}_2$  is transported by hemoglobin to cells in the peripheral tissues, myocytes bind  $\text{O}_2$  for intracellular utilization, mitochondrial proteins of the electron transport chain bind  $\text{O}_2$  for energy production and P450 enzymes bind  $\text{O}_2$  for its use in phase I metabolism of endogenous and xenobiotic chemicals. However, because of its reactivity, iron in its ferrous state must be carefully sequestered away to prevent the formation of highly ROS which can elicit severe cellular damage. Ferrous iron ( $\text{Fe}^{2+}$ ) and other transition metal ions,  $\text{Cu}^+$ ,  $\text{Cr}^{5+}$ ,  $\text{Ni}^{2+}$  or  $\text{Mn}^{2+}$ , can catalyze the formation of hydroxyl ion ( $\text{HO}^-$ ) and the extremely reactive and dangerous hydroxyl radical ( $\text{HO}^\bullet$ ) from the reduction of endogenous hydrogen peroxide ( $\text{HOOH}$ ) via the *Fenton reaction*:

The Fenton reaction causes site-specific accumulation of free radicals and initiates biomolecular damage. Free radicals are molecules or molecular fragments that contain one or more unpaired electrons in their outer orbital shell. If produced in great enough quantities to overwhelm the cellular antioxidant and radical-quenching protective mechanisms, hydroxyl radicals promote the formation of more hydroxyl radicals and other ROS such as superoxide. Superoxide combines with nitric oxide and forms peroxynitrite, which is as detrimental as hydroxyl radical. These ROS/RNS damage and destroy proteins and DNA by causing cross-linking, which inhibits their normal functions, or by initiating extensive damage and spontaneous degeneration of molecules such as lipids (Avery, 2011). ROS/RNS not only cause DNA damage, but also inhibit repair activities. ROS induce lipid peroxidation which if not quenched can initiate a chain reaction of lipid destruction and ROS formation

destroying vital cell membranes in mitochondria, nuclei and the cell periphery. Together, these effects can be of great enough magnitude to cause cell death, organ dysfunction and death. However, it is also of interest to note that iron is necessary for the normal functioning of macrophages and other leucocytes during the respiratory burst in inflammation to catalyze the formation of bactericidal hydroxyl radical (Gregus and Klaassen, 2001).

## TOXICITY

### General

Iron poisoning is not common in animals although potentially it could occur in any species. Clinical cases of acute iron toxicosis have been reported in dogs, pigs, horses, cattle and goats (Greentree and Hall, 1983; Ruhr *et al.*, 1983; Osweiler *et al.*, 1985; Holter *et al.*, 1990). Toxicity can occur through ingestion or parenteral administration. Because of their indiscriminate eating habits and close proximity to people and their nutritional supplements, dogs are the species most likely to ingest large quantities of iron-containing vitamins. Baby pigs are iron deficient at birth and require iron supplementation, which can result in peracute or acute toxicity. Limited cases of iron poisoning have occurred in horses and cattle through the use of iron supplements. In general, toxicity occurs in the GI mucosa (oral exposure), liver, myocardium and other tissues when the iron-binding capacity of the body is overwhelmed, and free iron causes oxidative damage. Genetic iron storage diseases are uncommon, but have been reported in mynah birds, toucans, Saler cattle, Egyptian fruit bats and rarely in horses.

### Acute toxicity in dogs, cattle, pigs and adult horses

Acute iron toxicity has been reported in dogs (Greentree and Hall, 1983), cattle (Ruhr *et al.*, 1983), pigs (Velasquez and Aranzazu, 2004), horses (Arnbjerg, 1981) and humans. In dogs, toxicosis primarily occurs through the accidental ingestion of large amounts of iron-containing vitamins or other iron supplements. In cattle, horses and pigs, it has occurred through accidental administration of excess amounts of iron supplements by oral or parenteral routes. Diagnosis is based on history, appropriate clinical signs and radiography in small animals as iron-containing pills are radiodense. In general, if the animals remain asymptomatic for greater than 8h following a single exposure, it is reported that they are unlikely to develop iron toxicity. In all species, ingestion of a toxic dose

(roughly greater than 20mg/kg in dogs) initially results in necrosis of the GI mucosal cells. This is followed by fluid loss, direct cardiotoxicity and widespread organ damage through the mechanisms described above. Fluid loss and decreased cardiac output can lead to circulatory shock. Iron toxicity has been described as occurring in four stages. Stage I occurs 0–6h post-ingestion and is characterized by vomiting, diarrhea, abdominal pain and depression. Stage II occurs from 6 to 24h post-ingestion and is characterized by apparent recovery. Stage III begins at 12–96h with commencement of additional vomiting, diarrhea, abdominal pain, GI hemorrhage, weakness, shock and possibly death. Stage IV, if it occurs, begins 2–6 weeks after ingestion and is characterized by GI fibrosis and obstruction (Greentree and Hall, 1983).

### Neonatal pigs

Paradoxically, iron toxicity in piglets resulting from oral supplementation or parenteral injection occurs because of the very low liver iron stores in newborn pigs and the need to supplement the small amounts of iron that they receive in sow's milk. Because of their low iron stores at birth, iron-deficiency anemia can occur in non-supplemented baby pigs within 2–4 weeks after birth. This is manifested clinically in the pigs as dyspnea, anorexia, increased infections and poor growth with some deaths. It is prevented by oral or parenteral injection of iron-containing compounds (Underwood, 1977; Osweiler *et al.*, 1985). When comparing routes of administration of the same iron compound the potential for toxicity is the greatest after intravenous injection followed by intramuscular injection with oral administration being the least toxic. In acute iron toxicosis of pigs, two syndromes are recognized. The first is a peracute syndrome which is characterized by sudden death minutes to a few hours after iron injection. In some ways this resembles an anaphylactic reaction in its rapidity of onset, vascular collapse and death, but the exact mechanism is not known. This peracute syndrome has also been reported in horses following administration of iron compounds (Lannek and Persson, 1972; Bergsjoe, 1974). The second syndrome described in pigs is a subacute to acute syndrome characterized by GI necrosis, severe depression, coma and death which can occur in the four stages described above. Pigs born to sows deficient in vitamin E and selenium are reported to be more susceptible to iron toxicosis (Osweiler *et al.*, 1985; Velasquez and Aranzazu, 2004).

### Neonatal horses

Although reports of iron toxicosis in horses and ponies are rare, several cases in the 1980s are of note. Newborn foals,

2–5 days old, were given an oral nutritional supplement containing ferrous fumarate. They became ill, icteric, weak and died of liver failure within 1–5 days following administration. The histologic lesions in the livers of these foals were remarkable in that they had the appearance of longer-term chronic lesions even though they were as little as 24 h old. These hepatic lesions consisted of prominent bile ductule proliferation, hepatic cell necrosis and periportal fibrosis (Divers *et al.*, 1983; Acland *et al.*, 1984). Through experimental administration, it was determined that ferrous fumarate, administered orally to foals within the first few days after birth, caused the liver failure seen in the earlier clinical cases (Mullaney and Brown, 1988). The increased sensitivity of the neonatal foals is thought to be from increased absorption in the GI tract and lower systemic iron-binding capacity (Poppenga, 2002). The iron overload in these foals resulting from oral administration of ferrous fumarate caused hepatic necrosis with bile ductule proliferation and fibrosis. It is speculated that what was histologically interpreted as proliferation of bile ductules was, in fact, proliferation of hepatic stem cells (oval cells) in response to the severe hepatic damage (personal observation). Experimentally, adult ponies have been administered iron as ferrous sulfate at 50 mg/kg/day orally for up to 8 weeks. Through the study and for 20 weeks after the end of dosing, no adverse clinical signs or hepatic damage were reported (Pearson and Andreasen, 2001).

### Iron storage disease

Iron storage disease resulting in hemosiderosis and hemochromatosis has been reported in several different species of animals. Hemochromatosis is the pathologic accumulation of iron in tissues, while hemosiderosis is the non-pathologic accumulation of iron. In birds, iron storage disease has been reported in mynah birds, toucans, birds of paradise and quetzals. The clinical signs are dyspnea, hepatic damage/insufficiency and death in mynah birds. Sudden death has been reported in toucans. It has been shown that the cause in mynah birds is due to maintenance of iron uptake from the GI tract, despite excess hepatic iron accumulation (Mete *et al.*, 2003). The treatment in birds can consist of a low iron diet with phlebotomy or the use of iron chelators (Rodenbusch *et al.*, 2004). A genetic, inheritable defect resulting in hemochromatosis, clinical wasting and skeletal defects can occur in Salers cattle beginning at 9–22 months of age (O'Toole *et al.*, 2001; Norrdin *et al.*, 2004). Egyptian fruit bats (*Rousettus aegyptiacus*) are also known to have genetic iron storage disease. In these bats, it was found that if the sum of transferrin saturation and serum iron was greater than 51, the individual bat had

a high probability of having iron overload. When the sum was greater than 90, there was a high probability of having hemochromatosis (Farina *et al.*, 2005). In addition, although rarely reported, hemochromatosis with liver damage has also been reported in horses (Pearson *et al.*, 1994) and captive northern fur seals (Mazzaro *et al.*, 2004). Finally, one case of hemochromatosis secondary to repeated blood transfusions every 6–8 weeks for 3 years for the treatment of red cell aplasia has been reported in an aged miniature schnauzer (Sprague *et al.*, 2003).

## TREATMENT

Treatment of iron toxicity varies with the inciting cause, dose and duration of the disease. General therapy is to limit absorption (although activated charcoal is ineffective at binding iron), provide symptomatic and supportive care, remove gastric bezoars of sticky iron-containing pills, surgically if necessary, and increase excretion. Because the body has limited ability to excrete excess iron (other than through bleeding), urinary excretion can be enhanced through the use of a chelating agent. A specific chelator of iron, deferoxamine has been used in the treatment of iron toxicity. Deferoxamine has a strong affinity for iron, a low affinity for calcium and competes effectively for iron in ferritin and hemosiderin, but not in transferrin, hemoglobin or heme-containing enzymes. It is poorly absorbed orally and so is given parenterally by slow intravenous drip. Since it is excreted primarily by the kidneys, it should be given carefully to patients with renal insufficiency (Osweiler *et al.*, 1985; Goyer and Clarkson, 2001; Poppenga, 2002).

## CONCLUDING REMARKS

Iron is essential for normal physiological functioning. Iron-deficiency anemia is common in humans and also occurs in piglets, veal calves and parasitized animals. Therefore, iron supplements are readily available and widely used. In addition, some species have a propensity for genetic iron storage diseases. Fortunately, both acute and chronic iron toxicoses are rare in animals. When toxicosis does occur, cellular damage is caused by the presence of free iron in excess of the body's capacity to bind and sequester it. The free iron then initiates the generation of ROS in excess of cellular oxidant defenses resulting in lipid peroxidation of membranes, protein and DNA cross-linking, and cell death.

# Lead

Larry J. Thompson

## INTRODUCTION

Lead is a bluish white to gray heavy metal that was probably the first toxic element recognized by man and yet still has great relevance today. The chemical symbol for lead, Pb, is short for the Latin word *plumbum*, meaning liquid silver. The main source of lead is the ore named galena, which contains lead sulfide. The main use of lead today is in lead-acid storage batteries but historically it has had widespread usage in paints (white, yellow and red pigments) and as a gasoline additive (tetraethyl lead) although these latter uses have essentially been phased out. A debate still continues as to the role lead played in the fall of the Roman Empire. Although lead was indeed used in some Roman water pipes (the word *plumbum* leading to our modern word plumber) the main source of lead for the Romans was probably sapa, a syrup used to sweeten wine and preserve fruit, which was made by boiling grape juice in lead pots thereby adding lead acetate to the liquid. The use of lead continues in our modern world with lead-containing solder in our electronics as well as lead-containing glass, from cathode ray tube monitors to fine crystal. Among all the metals, lead poisoning is encountered with greatest frequency in certain species of animals and poses a serious concern to animal health. This chapter describes the toxicity of lead in mammalian and avian species.

## BACKGROUND

Lead is a toxic element and has not been shown to be an essential trace element for nutrition. The historical use of lead in gasoline, paint, construction materials and many

other products has resulted in lead being one of the most significant environmental contaminants in the world. Additional sources of lead have included lead weights (e.g., for fishing or curtains), small lead trinkets and toys, lead shot and bullets for weapons, lead arsenate pesticides and many other products as well as single source environmental contamination from mining, smelting and recycling operations. As a result of increased regulation of lead and the decreasing use of lead-containing products, the overall incidence of lead poisoning (also called plumbism) in animals and humans has been decreasing. While environmental contamination with lead does not resolve readily, the overt poisoning of domestic animals from environmental sources (e.g., from contaminated forages, plants, water or other food sources) has been decreasing in number. Still, lead poisoning in animals is encountered with greatest frequency compared to any other metal.

## TOXICOKINETICS

The main route of entry of lead into the body is the digestive tract with absorption dependent upon the chemical form of lead and the physiological state of the animal. Organic lead compounds are, in general, more readily absorbed than either inorganic lead salts or the metallic form of lead. Dermal absorption of organolead compounds can be significant but the salt or metallic forms of lead are not absorbed dermally. The fumes from heated lead or very fine particles ( $<0.5\mu\text{m}$ ) of lead can enter the lung alveoli and be absorbed with the larger particles lodging in the ciliated portion of the bronchial tree. These larger particles can be transported up by mucociliary action and then swallowed with absorption through

the gastrointestinal tract. Fine particles of lead and lead salts can be solubilized in the acid environment of the stomach and the small intestine is the site of most lead absorption. Absorption of lead from the alimentary tract is usually influenced by dietary factors and by the size of lead particles. High dietary fat and mineral deficiency can increase lead absorption by seven- and 20-fold, respectively. In an experimental study, dogs maintained on a high-fat, low-calcium diet absorbed significantly more lead than those kept on a balanced diet (Hamir *et al.*, 1988). Young animals absorb a larger portion of the lead from the gastrointestinal tract than do adults. Animals with a calcium deficiency have increased absorption of lead. Pregnancy or lactation as well as deficiencies of iron, zinc or vitamin D can also enhance lead absorption. Lead crosses the placental barrier and the residue can be detected in significant amounts in fetal blood and organs. Among the fetal organs, the highest concentrations are found in the blood and liver (Kelman and Walter, 1980; O'Hara *et al.*, 1995; Flora *et al.*, 2011). Lead also passes through the milk.

Nonruminant animals absorb approximately 10% of dietary lead, and ruminants absorb less than 3%. Young animals can absorb up to 90% of the ingested lead. Following absorption, a large proportion of lead is carried on erythrocyte membranes (60–90%, species dependent) with most of the remainder of lead bound to protein or sulfhydryl compounds, with only a very small proportion found free in the serum. Lead is widely distributed in the body, including crossing the blood–brain barrier (Seimiya *et al.*, 1991). In the soft tissues lead binds to various proteins as well as metallothionein but accumulates in the active bone matrix (about 90%) serving as a relatively inert reservoir of lead in the body. This reservoir can be mobilized by lactation, pregnancy or the action of chelating agents. Otherwise lead has a very slow turnover rate from the bone. Lead is normally very slowly excreted via the bile with very little in the urine. Chelation therapy greatly increases the urinary output of lead.

## MECHANISM OF ACTION

Lead interferes with several biochemical processes in the body by binding to sulfhydryl and other nucleophilic functional groups causing inhibition of several enzymes and changes in calcium/vitamin D metabolism. Lead also contributes to oxidative stress within the body. Lead inhibits the body's ability to make hemoglobin by interfering with several enzymatic steps in the heme pathway. Specifically, lead decreases heme biosynthesis by inhibiting delta-aminolevulinic acid dehydratase and ferrochelatase activity. These changes contribute to the anemia

that develops in chronic lead poisoning. An increased fragility of red blood cells also contributes to the anemia.

From various experimental studies, biochemical and pathological evidence suggests that lead is neurotoxicant, as it significantly disrupts certain brain structures and functions. High-dose exposure to lead (i.e., blood levels in excess of 4  $\mu$ M) disrupts the blood–brain barrier. Molecules such as albumin that normally are excluded freely enter the brain of immature animals exposed to these concentrations of lead (Clasen *et al.*, 1973; Goldstein *et al.*, 1974; Bressler and Goldstein, 1991). Ions and water follow and edema is produced. Intracranial pressure rises as edema accumulates in the brain because of the physical restraint of the skull. When the intracranial pressure approaches the systemic pressure, cerebral perfusion decreases and brain ischemia occurs.

Many of the neurotoxic effects of lead appear related to the ability of lead to mimic or in some cases inhibit the action of calcium as a regulator of cell function (Bressler and Goldstein, 1991). At a neuronal level, exposure to lead alters the release of neurotransmitters (dopamine, acetylcholine and  $\gamma$ -aminobutyric acid) from nerve endings. Spontaneous release is enhanced and evoked release is inhibited. The former may be due to activation of protein kinases in the nerve endings and the latter to blockade of voltage-dependent calcium channels.

Brain homeostatic mechanisms are disrupted by exposure to higher levels of lead. The final pathway appears to be a breakdown in the blood–brain barrier. Again, the ability of lead to mimic or mobilize calcium and activate protein kinases may alter the properties of endothelial cells, especially in immature brain, and disrupt the barrier. In addition to a direct toxic effect upon the endothelial cells, lead may alter indirectly the microvasculature by damaging the astrocytes that provide signals for the maintenance of blood–brain barrier integrity, and necrosis in neurons with shrunken cytoplasm, pyknotic nuclei and increased perineuronal space.

Recent studies provided evidence of increased production of reactive oxygen species (ROS) following lead exposure. Lead induced oxidative damage in several tissues by enhancing lipid peroxidation through Fenton reaction or by direct participation in free radical-mediated reactions, such as inhibition of  $\delta$ -aminolevulinic acid dehydratase (ALAD) activity or accumulation of ALA, a metabolite that can release  $\text{Fe}^{2+}$  from ferritin, and induce oxidative damage.

## TOXICITY

Mammals, birds and reptiles have all been found to develop lead poisoning. The toxic dose of lead has been

determined for several species but is difficult to apply to clinical cases where the exposure history is unclear (Gwaltney-Brant, 2004). In general, young animals are more susceptible to lead toxicosis because they are more prone to lead pica and have a higher rate of absorption (about 90%) from the intestinal tract. Cattle have been most widely reported with lead toxicosis, probably due to their propensity to ingest discarded lead-acid batteries and construction materials including paints. Dogs are also commonly reported with lead toxicosis, probably due to their chewing habits and ingestion of small lead objects around the house. Both cats and dogs have been exposed to lead by the renovations of older homes containing leaded paints. The main route seems to be the ingestion of fine dust by the grooming habits of indoor pets and their tendency to ingest small objects.

Clinical signs of lead toxicosis vary with the species involved, duration of exposure and amount of lead absorbed. The major systems affected by lead poisoning are the gastrointestinal system, central nervous system and hematological system. Abdominal pain and diarrhea can be common clinical signs in animals exposed to excess lead. Anorexia is common as well as vomiting in those species that are able to. Neurological signs including depression, weakness and ataxia can progress to more severe clinical signs of muscle tremors or fasciculations, head pressing (especially in ruminants), blindness, seizure-like activity and death. Many animals with chronic lead poisoning will show subtle and non-specific clinical signs such as abdominal discomfort, vague gastrointestinal upsets, anorexia, lethargy, weight loss and behavior changes. Horses develop acute lead toxicosis and show clinical signs of laryngeal paralysis and "roaring," in addition to colic and seizure-like activity. Evidence suggests that horses may be more susceptible to chronic lead toxicosis than cattle. Horses exposed to daily intake as low as 1.7 mg/kg body weight (approximately 80 ppm Pb in forage dry matter) were poisoned (Aronson, 1972). Clinical signs of lead toxicosis in avians vary with waterfowl and raptors mainly displaying a chronic wasting disorder with apparent peripheral neuropathy. Psittacines are more likely to display gastrointestinal problems and neurological abnormalities.

Gross lesions in animals dying of lead poisoning are often minimal and non-specific, although lead-containing objects may be visible in the gastrointestinal tract. Histologically, there may be degeneration and necrosis of the renal tubular epithelium or the presence of acid-fast inclusion bodies (Hamir *et al.*, 1988; O'Hara *et al.*, 1995). Brain lesions in a calf poisoned with lead included multiple focal or laminar lesions of neuronal necrosis in the cerebral cortex, caudatum and medial nuclei of thalamus, predominantly at the tips of gyri in the occipital and parietal lobes. The lesions spread occasionally to the deeper region of the gyri along the

sulci (Seimiya *et al.*, 1991). The affected neurons were shrunken and angular, sometimes triangular in outline with pale eosinophilic cytoplasm. The nuclei showed pyknosis and rhexis. Edematous dilation of perivascular and perineuronal spaces with spongiotic state of neuropil was observed from the molecular layer to outer zone of the white matter. Astrocytic proliferation was also observed. Blood capillaries were congested with enlarged and increased endothelial cells. Meningeal blood vessels were prominently congested with mild lymphocytic infiltration. Edema of Purkinje cell layer in the cerebellum and mild neuronal degeneration in the nucleus of mesencephalon were seen.

Lead is also a reproductive and developmental toxicant and details can be found in a recent publication (Flora *et al.*, 2011).

Diagnosis of lead poisoning in animals should be made with a combination of history, clinical or necropsy findings, and lead analysis of tissue. Basophilic stippling of erythrocytes and inhibition of hemoglobin synthesis are characteristic hematological features of lead poisoning. From a living animal, whole blood is the best sample for laboratory determination of lead. The normal background concentration of lead in the blood of mammals is below 0.1 ppm. With clinically affected animals, lead concentrations above 0.35 ppm are compatible with a diagnosis of lead toxicosis. Postmortem samples of choice are kidney and liver with lead concentrations above 10 ppm on a wet weight basis being diagnostic for lead toxicosis in domestic species.

## TREATMENT

Acute lead poisoning in animals is usually fatal if the animals are not treated promptly. Treatment approach for lead poisoning in animals includes stabilizing and supporting the animal especially if severe clinical signs are present, preventing additional exposure to lead and chelation therapy to quickly reduce the body burden of lead. The exposure history of the animal should be reviewed for potential sources of lead and the need for gastrointestinal decontamination. The use of chelating agents when large amounts of lead are present in the gastrointestinal tract may actually enhance the absorption of lead into the body. Physical removal of lead-containing objects by surgical means may be necessary with larger objects. The parenteral use of calcium disodium ethylenediaminetetraacetic acid (CaEDTA) has been commonly used for several decades as a chelation agent in domestic animals (Kowalczyk, 1984).

Although other chelators may be superior, CaEDTA is still widely used in veterinary medicine, especially

in large animals. CaEDTA is given intravenously (IV) or subcutaneously (SQ) and chelates and mobilizes the lead from bone resulting in a transient increase in blood lead levels. This increase in blood lead can increase soft tissue lead levels leading to an exacerbation of clinical signs. Preceding CaEDTA usage with a chelator that specifically targets lead in the soft tissue (e.g., British Anti-Lewisite or BAL) has been recommended but is difficult to accomplish in most practice settings. CaEDTA can be nephrotoxic, especially in situations where the animal is dehydrated. Recommended treatment with CaEDTA for large animals is 73 mg/kg/day, divided into two or three doses given over the course of a day given by slow IV. For example, a 6.6% solution of CaEDTA (in normal saline or 5% dextrose) can be given IV at a rate of 1 ml per 2 pounds (0.9 kg) of body weight per day, in divided doses. Treatment should continue for 3–5 days. If additional treatment is needed, a rest period of 2 days with continued supported care is suggested before the additional 3–5-day second treatment period. An alternative treatment regimen is to administer CaEDTA at 110 mg/kg IV twice daily for 2 days. If additional treatment is needed, first apply the 2-day rest period of supportive care before initiating the second treatment period of 2 days at 110 mg/kg twice daily. Thiamine has been shown to be a valuable adjunct to the treatment of lead poisoning in ruminants (Bratton *et al.*, 1981) and is recommended for other species as well. A dose of 2 mg/kg/day for calves and 250–2000 mg/day for adult cattle has been recommended.

If commercial CaEDTA is unavailable, a stock solution can be formulated for emergency antidotal usage. A 10% stock solution can be made by dissolving 101.1 g of tetrasodium EDTA (Na<sub>4</sub>EDTA) plus 30 g of anhydrous calcium chloride (CaCl<sub>2</sub>) in distilled water to a final volume of 1000 ml. From the stock solution a working 2.22% solution can be made by mixing 220 ml of the 10% stock solution with 780 ml distilled water. Using the 2.22% solution, the daily dosage of 73 mg/kg/day is equal to approximately 3.5 ml/kg of body weight. This should be divided into two or three separate administrations (Thompson, 1992). Tetrasodium EDTA should never be administered by itself as it may cause hypocalcemia.

Recommended treatment with CaEDTA for dogs is 100 mg/kg/day in four divided doses. Treatment should continue for 2–5 days and a second round of treatment is rarely needed but a 5-day rest period is recommended before applying additional treatment. CaEDTA concentration should be 10 mg/ml and may be administered by slow IV or by SQ route. Cats can be treated with 27.5 mg in 15 ml normal saline or 5% dextrose SQ every 6 h for 5 days or the same dose as a slow IV infusion.

Succimer (meso-2,3-dimercaptosuccinic or DMSA) is an orally administered chelating agent that is less likely to have adverse side effects associated with CaEDTA. The recommended treatment in dogs is an oral dose of

succimer at 10 mg/kg, repeated three times daily for 10 days (Ramsey *et al.*, 1996). Succimer has also been used orally in caged birds at a dose of 25–35 mg/kg twice daily for 5 days. Several weeks of therapy may be needed in avians. In initial experimental work, succimer given to experimentally lead-poisoned calves IV at 25 mg/kg/day for 4 days was more effective than CaEDTA at decreasing lead concentrations in the liver and kidney (Meldrum and Ko, 2003).

In a recent experimental study, Pachauri *et al.* (2009) provided evidence of the efficacy of combinational therapy using an antioxidant with a thiol chelator in reversing neurological dystrophy caused by chronic lead exposure in rats.

## CONCLUDING REMARKS

While cases of lead toxicosis in animals have been decreasing, it should remain on the clinician's list of rule-outs for seizure-like activity, blindness and vague neurological and gastrointestinal disorders. At a minimum, the environment of the animal should be reviewed for possible lead sources.

# Manganese

*Dejan Milatovic and Ramesh C. Gupta*

## INTRODUCTION AND BACKGROUND

Manganese (Mn) was discovered by Sheele in Sweden in 1774. Mn has an atomic number of 25 and has two oxidation states: Mn(0) and Mn<sup>2+</sup>. It does not occur naturally in a pure state or as a metal, but as a component of over 100 minerals (ATSDR, 2000). The most important Mn-containing minerals are oxides, carbonates and silicates (Post, 1999). Mn is abundantly found in the environment, including rocks, soil, water and food, with the highest concentrations typically in nuts, cereals, grains, fruits, vegetables and tea. Mn is a component of certain aluminum alloys, particularly those used in the manufacture of soft drink cans. Inorganic Mn is also used in dry cell batteries, animal feed, brick coloring and fertilizers (ATSDR, 2000; Corathers, 2001). Organic Mn is used as a fuel additive and in fungicides, such as macozebe and maneb (ATSDR, 2000; Kaiser, 2003).

Mn is an essential element for maintaining the proper function and regulation of many biochemical and cellular reactions (Takeda, 2003) that are critical for humans, animals and plants. It is required for growth and development and plays a role in immune response, blood sugar homeostasis, adenosine triphosphate (ATP) regulation, digestion, bone growth, reproduction and lactation. It is a necessary component of numerous metalloenzymes, such as Mn superoxide dismutase, arginase, phosphoenol-pyruvate carboxylase and glutamine synthase (Aschner and Aschner, 2005). As a result, dietary deficiency of Mn is known to affect several enzymes, including glycosyltransferases, xylosyltransferases, arginase and mitochondrial superoxide dismutase (NRC, 2005). The dietary requirement of Mn is

10ppm in rats and mice, 40ppm in guinea pigs, 20ppm in pigs, 28–30ppm in chickens, 20ppm in beef cattle and 40ppm in dairy cattle. Practically, Mn deficiency occurs more frequently in cattle, pigs and poultry. In ruminants, Mn deficiency can be linked to silent heat, reduced conception, abortions, reduced birth weight, an increased percentage of male calves, paralysis and skeletal damage in calves. Mn deficiency can cause delayed estrus, reduced fertility and spontaneous abortions in mares. Foals are born with skeletal deformities and muscle contractures, such as asymmetry of the skull, curvature of the vertebral column, shortened limb bones, enlarged joints and contracture of neck muscles. In dogs, Mn deficiency can cause crooked and shortened soft bones (Puls, 1994).

Despite its essentiality, Mn overexposure can cause a variety of toxic effects in humans and animals. Mn has been linked to a peculiar extrapyramidal syndrome in occupational workers since 1837. Since then, incidences of Mn poisoning, especially in mines and steel factories, have been reported in many countries. Fortunately, in the last three decades there has been a declining trend even in developing countries. Mn poisoning can occur in animals or humans if the exposure level of Mn exceeds the normal levels in the environment. Toxicity can also occur if either the dietary concentration exceeds the maximal tolerable levels or if dietary intake of other minerals is marginal (Hartman *et al.*, 1955; Ivan and Hidiroglou, 1980; Southern and Baker, 1983; Baker and Halpin, 1991; Hauser *et al.*, 1994). The brain, in particular, is highly susceptible to Mn toxicity. Excessive accumulation of Mn in specific brain areas, such as the substantia nigra, the globus pallidus and the striatum, produce neurotoxicity leading to a degenerative brain disorder, referred to as

manganism. In addition to neurological effects, Mn accumulation is also associated with reproductive and developmental effects. High-dose exposure to Mn has been associated with increased fetal brain Mn concentrations (Kontur and Fechter, 1985) although several studies have reported an ability of the placenta to reduce systemic delivery of Mn to the fetal brain. Moreover, Mn plays a role in the modulation of the immune system, and in protein, lipid and carbohydrate metabolism (Address *et al.*, 1997; Malecki *et al.*, 1999; Aschner *et al.*, 2002; Fitsanakis and Aschner, 2005). This chapter describes deficiency and toxicity of Mn in animals.

## PHARMACOKINETICS/ TOXICOKINETICS

Absorption of Mn is via oral and inhalation routes. Absorption of Mn through the skin is negligible. Apparent absorption of orally administered  $^{54}\text{Mn}$  has been estimated to range from 1 to 5% in rats, humans and livestock (Hurley and Keen, 1987; Davis *et al.*, 1993). In young rats, Mn absorption has been reported to be 8%. Absorption of Mn appears to occur by a low-capacity saturable process and by diffusion (Garcia-Aranda *et al.*, 1983; ATSDR, 2000). Uptake and retention of dietary Mn was found to be greater in suckling than post-weaning rats (Keen *et al.*, 1986). In cattle, using  $\text{MnSO}_4$  as 100% available,  $\text{MnO}$  is 58%,  $\text{MnO}_2$  is 33% and  $\text{MnCO}_2$  is 28% available (Puls, 1994). Mn is more available from hay to cattle than from silage. It is important to note that newborn calves absorb and retain more dietary Mn than adults.

Absorption of Mn can be influenced by various dietary factors, such as iron, calcium, phosphorus, phytate and amino acids. Henry (1995) estimated the relative bioavailability of Mn to poultry was 0.55 from manganese carbonate, 0.3 from manganese dioxide and 0.75 from manganese monoxide, when the bioavailability of manganese from manganese sulfate and manganese chloride was considered to be 1. Manganese from manganese carbonate, dioxide and monoxide (relative bioavailabilities were 0.3, 0.35 and 0.6, respectively) was even less available to sheep than manganese sulfate (relative bioavailability was 1).

Following absorption, Mn can be distributed to many organs. The average adult human has about 12 mg of Mn, of which about 43% resides in the skeletal system and the rest in soft tissues including the liver, pancreas, kidneys and central nervous system (CNS). Such information about Mn is not available for animals. It is interesting to note that in dogs, the pancreas accumulates 3–60 times more Mn than other soft tissues. Furthermore, colored hair has higher Mn levels than non-colored hair.

After absorption from the gut, Mn is transported to the liver by  $\alpha_2$ -macroglobulins and albumin (Andersen *et al.*, 1999). This protein-bound Mn is efficiently cleared in the liver and is bound to transferrin. Transferrin is believed to be the primary transporter of Mn across the blood–brain barrier (BBB) and Mn is taken up into astrocytes and neurons in the brain. Astrocytes serve as the major homeostatic regulator and storage site for Mn in the brain. Increased accumulation of Mn in astrocytes may alter release of glutamate and elicit excitatory neurotoxicity (Erikson and Aschner, 2003). Neuronal uptake of Mn involves transferrin (Suarez and Eriksson, 1993) and utilization of specific transporter systems, such as the dopamine transporter (Chen *et al.*, 2006a; Anderson *et al.*, 2007). At the subcellular level, Mn preferentially accumulates in mitochondria, where it disrupts oxidative phosphorylation and increases the generation of reactive oxygen species (ROS) (Gunter *et al.*, 2006).

Rodent studies of enhanced CNS uptake during development have been contradictory. While one study indicates that the amount of Mn that crosses the placenta was not increased by enhanced maternal exposure via diet (Jarvinen and Ahlstrom, 1975), another study indicated increased neonatal brain Mn following chronic high-level exposure of the dam to Mn in drinking water throughout gestation (Kontur and Fechter, 1985). Other studies also showed that, when compared with adults, neonatal rodents attain higher brain Mn levels following similar oral exposures (Kontur and Fechter, 1985; Dorman *et al.*, 2000). This tendency of neonates to attain higher brain Mn concentrations may reflect a less than optimal BBB, markedly reduced biliary Mn excretion rates, and/or increased placental Mn concentration (Aschner and Aschner, 2005). However, an increase in the placental concentrations does not necessarily mean higher placental transfer of Mn to the fetus or higher fetal exposure (Dorman *et al.*, 2005; Yoon *et al.*, 2009a). Furthermore, brain Mn concentrations are higher in developing animals, suggesting that high amounts of Mn are required for normal brain development in infants (Keen *et al.*, 1986; Takeda *et al.*, 1999). Therefore, whether the relatively higher net increase in brain Mn observed in neonates compared to adults would pose an increased risk for neurotoxicity requires further understanding of the Mn requirements for normal brain development (Yoon *et al.*, 2009b).

The absorbed Mn can be excreted via urine and bile. Excretion of Mn through urine is minor. Bile is the major excretory route of injected or ingested Mn. Rats excreted 15–40% (Ballatori *et al.*, 1987) and calves excreted 21% (Abrams *et al.*, 1977) of injected doses of Mn in bile. In humans, Mn is eliminated almost entirely with feces, and only 0.1–1.3% of daily intake through urine. Klaassen (1974) observed that rats excreted proportionately more Mn into bile than rabbits and dogs. Following ingestion, effectiveness of the gut in preventing excess

absorption blunts the effect of biliary excretion (Abrams *et al.*, 1977; Davis *et al.*, 1993; Malecki *et al.*, 1996). Calves excreted 0.2% of a duodenal dose of Mn into bile in one study (Abrams *et al.*, 1977) and 2.1–3.6% of high levels of Mn infused intraduodenally in another study (Symonds and Hall, 1983).

## MECHANISM OF ACTION

Mn is generally described as a neurotoxicant, selectively affecting basal ganglia structures. Although it is known that Mn is a cellular toxicant which can impair the transport system, enzyme activity and receptors function, the principal mechanism by which Mn neurotoxicity occurs has not yet been clearly established (Aschner and Aschner, 1991; Aschner *et al.*, 2007). Since mitochondria are the principal intracellular repository for metals (Cotzias and Greenough, 1958), binding of Mn to inner mitochondrial membrane or matrix proteins (Gavin *et al.*, 1990) directly interacts with proteins involved in oxidative phosphorylation. Mn directly inhibits complex II (Singh *et al.*, 1974) and complexes I–IV (Zhang *et al.*, 2003) in brain mitochondria, and suppresses ATP-dependent calcium waves in astrocytes, suggesting that Mn promotes potentially disruptive mitochondrial sequestration of calcium (Tjalkens *et al.*, 2006). Elevated matrix calcium increases the formation of ROS by the electron transport chain (ETC) (Kowaltowski *et al.*, 1995) and results in inhibition of aerobic respiration (Kruman and Mattson, 1999). Recent studies with primary astrocytes and neurons have shown that Mn exposure induces an increase in the biomarkers of oxidative stress (Milatovic *et al.*, 2007, 2009). Measurement of F<sub>2</sub>-isoprostanes (F<sub>2</sub>-IsoPs) (Morrow and Roberts, 1999; Milatovic and Aschner, 2009), a group of arachidonic acid-derived prostanoid isomers generated by free radical damage due to arachidonic acid, revealed that astrocytes exposed to Mn at neurotoxic level (100  $\mu$ M, 500  $\mu$ M or 1 mM) induced significant elevations in F<sub>2</sub>-IsoPs (Figure 38.1). Thus, increases in ROS, which are generated by electron leak from the ETC (Turrens and Boveris, 1980), potentially damaging mitochondria directly or through the effects of secondary oxidants like superoxide, H<sub>2</sub>O<sub>2</sub> or peroxynitrite (ONOO<sup>-</sup>), mediate Mn-induced oxidative damage. Moreover, superoxide produced in the mitochondrial electron transport chain may catalyze the transition shift of Mn<sup>2+</sup> to Mn<sup>3+</sup> through a set of reactions similar to those mediated by superoxide dismutase and thus lead to the increased oxidant capacity of this metal (Gunter *et al.*, 2006). Consequent oxidative damage produces an array of deleterious effects: it may cause structural and functional derangement of the phospholipids bilayer of membranes, disrupt energy metabolism, metabolite biosynthesis,

**FIGURE 38.1** Effects of MnCl<sub>2</sub> on F<sub>2</sub>-IsoPs formation in cultured astrocytes. Rat primary astrocyte cultures were incubated at 37°C in the absence or presence of MnCl<sub>2</sub> (100  $\mu$ M, 500  $\mu$ M or 1 mM), and F<sub>2</sub>-IsoPs levels were quantified at 30 min, 2 h and 6 h. Data represent the mean  $\pm$  S.E.M. from three independent experiments. \*Significant difference between values from control and Mn-treated astrocytes (\**p* < 0.05).

calcium and iron homeostasis and initiate apoptosis (Attardi and Schatz, 1988; Yang *et al.*, 1997; Uchida, 2003).

Consistent and preceding the Mn-induced increased in biomarkers of oxidative damage (F<sub>2</sub>-IsoPs) (Figure 38.1), Milatovic *et al.* (2007) demonstrated an early decrease in astrocytic ATP levels. As a consequence, ATP depletion or a perturbation in energy metabolism might diminish the ATP-requiring neuroprotective action of astrocytes, such as glutamate and glutamine uptake and free radical scavenging (Rao *et al.*, 2001). In addition, depletion of high-energy phosphates may affect intracellular Ca<sup>2+</sup> in astrocytes through mechanisms involving the disruption of mitochondrial Ca<sup>2+</sup> signaling. This assertion is supported by data showing that Mn inhibits Na<sup>+</sup>-dependent Ca<sup>2+</sup> efflux (Gavin *et al.*, 1990) and respiration in brain mitochondria (Zhang *et al.*, 2004), both critical for maintaining normal ATP levels and ensuring adequate inter-mitochondrial signaling. Decrease in ATP following Mn exposure is also associated with excitotoxicity, suggesting a direct effect on astrocytes with subsequent impairment of neuronal function. Mn down-regulates the L-glutamate/L-aspartate transporter in astrocytes (Erikson and Aschner, 2002) and decreases levels of glutamine synthase in exposed primates (Erikson *et al.*, 2008). Studies with a neonatal rat model indicated that both pinacidil, a K<sup>+</sup> channel agonist, and nimodipine, a Ca<sup>2+</sup> channel antagonist, reversed Mn neurotoxicity and loss of glutamine synthase activity, further indicating excitotoxicity in the mechanism of Mn-induced neurotoxicity. Excessive Mn may lead to excitotoxic neuronal injury both by decreased astrocytic glutamate uptake and by loss of ATP-mediated inhibition of glutamatergic synapses.

Another consequence of Mn-associated increased oxidative stress and mitochondrial energy failure is the induction of the mitochondrial permeability transition (MPT), a  $\text{Ca}^{2+}$ -dependent process characterized by the opening of the permeability transition pore (PTP) in the inner mitochondrial membrane. This process results in increased permeability to protons, ions and other solutes (Zoratti and Szabo, 1995), which subsequently leads to a collapse of the mitochondrial inner membrane potential ( $\Delta\Psi_m$ ). Loss of the  $\Delta\Psi_m$  results in colloid osmotic swelling of the mitochondria matrix, movement of metabolites across the inner membrane, defective oxidative phosphorylation, cessation of ATP synthesis and further generation of ROS. Researchers have shown a concentration-dependent effect of Mn on the mitochondrial inner membrane potential in cultured astrocytes (Rao and Norenberg, 2004; Milatovic *et al.*, 2007). Zhang *et al.* (2004) revealed that high levels of Mn chloride (1 mM) cause a significant dissipation of the  $\Delta\Psi_m$  in isolated rat brain mitochondria, consistent with induction of the MPT.

Oxidative stress as an important mechanism in Mn-induced neurotoxicity has also been confirmed in the *in vivo* model. Analyses of cerebral biomarkers of oxidative damage revealed that a one-time challenge of mice with Mn (100 mg/kg) was sufficient to produce significant increases in  $\text{F}_2$ -IsoPs (Table 38.1) 24 hours following the last injection. Increased striatal concentrations of ascorbic acid and glutathione (GSH), antioxidants that when increased signal the presence of an elevated burden from ROS, as well as other markers of oxidative stress, have been previously reported (Desole *et al.*, 1994; Dobson *et al.*, 2004; Erikson *et al.*, 2007). Mn-induced decrease in GSH and increased metallothionein was reported in rats (Dobson *et al.*, 2003) and nonhuman primate studies (Erikson *et al.*, 2007). ROS may act in concert with reactive nitrogen species (RNS) derived from astroglia and microglia to facilitate the Mn-induced degeneration of dopaminergic (DAergic) neurons. DAergic neurons possess reduced antioxidant capacity, as evidenced by low intracellular GSH, which renders these neurons more vulnerable to oxidative stress and glial activation relative to other cell types (Sloot *et al.*, 1994; Greenamyre *et al.*, 1999). Therefore, the overactivation of glia and release of additional neurotoxic factors may represent a crucial component associated with the degenerative process of DAergic neurons.

Mn-induced ROS generation is also associated with inflammatory responses and release of inflammatory mediators, including prostaglandins. Recent studies confirmed that in parallel with an increase in biomarkers of oxidative damage, Mn exposure also induced an increase in biomarkers of inflammation, prostaglandin  $\text{E}_2$  ( $\text{PGE}_2$ ), *in vitro* and *in vivo* (Milatovic *et al.*, 2007, 2009). Results from an *in vivo* study showed that Mn exposure induced a time-dependent increase in  $\text{PGE}_2$

TABLE 38.1 Cerebral  $\text{F}_2$ -IsoPs and  $\text{PGE}_2$  levels in saline (control) or MnCl<sub>2</sub> (100 mg/kg, sc) exposed mice. Brains from mice exposed once or three times (day 1, 4 and 7) to MnCl<sub>2</sub> were collected 24 h post last injection

Exposure	$\text{F}_2$ -IsoPs (ng/ g tissue)	$\text{PGE}_2$ (ng/g tissue)
Control (saline)	3.013 + 0.03939	9.488 + 0.3091
Single Mn	4.302 + 0.3900*	12.03 + 0.4987*
Multiple Mn	4.211 + 0.4013*	14.22 + 1.019*

Values of  $\text{F}_2$ -IsoPs represent mean  $\pm$  SEM ( $n = 4-6$ ).

\*Significant difference between values from control and Mn-treated mice (\* $p < 0.05$ ).

(Table 38.1). Recent studies have also shown an inflammatory response of glial cells following Mn exposure (Chen *et al.*, 2006b; Zhang *et al.*, 2009; Zhao *et al.*, 2009). Mn potentiates lipopolysaccharide-induced increases in proinflammatory cytokines in glial cultures (Filipov *et al.*, 2005) and increases in nitric oxide production (Chang and Liu, 1999). An increase in proinflammatory genes, such as tumor necrosis factor- $\alpha$ , iNOS and activated inflammatory proteins such as P-p38, P-ERK and P-JNK have been measured in primary rat glial cells after Mn exposure (Chen *et al.*, 2006b). However, data from a recent study indicate that release of proinflammatory mediators following Mn exposure is not only associated with glial response, but neurons as well, and suggests that these two events are mechanistically related, with neuroinflammation either alone or in combination with activated glial response contributing to oxidative damage and consequent cell injury.

Dysregulation of excitatory glutamatergic neurotransmission by Mn is also associated with DAergic and GABAergic neuronal dysfunction. It is known that *in vitro* Mn can promote autooxidation of dopamine, which leads to the creation of reactive quinones (Miller *et al.*, 1990; Shen and Dryhurst, 1998). However, rodent and nonhuman primate data offer conflicting evidence on the influence of Mn exposure on catecholamine concentrations (Olanow *et al.*, 1996; Struve *et al.*, 2007). Additional evidence from nonhuman primate data suggests an Mn-induced postsynaptic decrease of D2-like dopamine receptor levels (Eriksson *et al.*, 1992). Several rodent studies support an association between Mn exposure and increased brain GABA concentration (Gwiazda *et al.*, 2002; Reaney *et al.*, 2006). However, other rodent studies suggested that Mn decreases striatal and frontal cortex GABA levels (Seth *et al.*, 1981; Brouillet *et al.*, 1993) or has no effect on GABA levels (Bonilla *et al.*, 1994). Additional findings also suggest that in the absence of extracellular  $\text{Ca}^{2+}$ , Mn induces a long-lasting potentiation of acetylcholine (ACh) release from cardiac parasympathetic nerve terminals following tetanic nerve stimulation (Kita *et al.*, 1981). In combination

**FIGURE 38.2** Photomicrographs of mouse striatal sections with representative tracings of medium spiny neurons (MSNs) from mice treated with saline (control) (A) or  $\text{MnCl}_2$  (100mg/kg, sc) (B). Brain from mouse exposed three times (day 1, 4 and 7) to  $\text{MnCl}_2$  was collected 24 h post last injection. Treatment with Mn induced degeneration of striatal dendritic system, decrease in total number of spines and length of dendrites of MSNs. Tracing and counting are done using a NeuroLucida system at 100 $\times$  under oil immersion (MicroBrightField, VT). Colors indicate the degree of dendritic branching (yellow = 1°, red = 2°, purple = 3°, green = 4°, turquoise = 5°).

with glutamate-gated cation channel activation, e.g., N-methyl-D-aspartate (NMDA) receptor, secondary excitotoxicity mechanisms play an important role in the development of Mn-induced neurodegeneration.

Neurotoxicity of Mn reflects alterations in the integrity of DAergic striatal neurons and DA neurochemistry, including decreased DA transport function and/or striatal DA levels. The striatum is a major recipient structure of neuronal afferents in the basal ganglia. It receives excitatory input from the cortex and DAergic input from substantia nigra and projects to the internal segment of the globus pallidus (Dimova *et al.*, 1993; Saka *et al.*, 2002). Nigrostriatal DAergic neurons appear to be particularly sensitive to Mn-induced toxicity (Sloot and Gramsbergen, 1994; Sloot *et al.*, 1994; Defazio *et al.*, 1996). Intense or prolonged Mn exposure in adulthood causes long-term reductions in striatal DA levels and induces a loss of autoreceptor control over DA release (Autissier *et al.*, 1982; Komura and Sakamoto, 1992). Nigrostriatal DA axons synapse onto striatal medium spiny neurons (MSNs), and these neurons have radially projecting dendrites that are densely studded with spines (Wilson and Groves, 1980). Recent data show the effects of Mn on degeneration of striatal neurons. Representative images of Golgi-impregnated striatal sections with their traced MSNs from control and Mn-exposed animals are presented in Figure 38.2. Images of neurons with NeuroLucida-assisted morphometry show that Mn-induced oxidative damage and neuroinflammation targeted the dendritic system with profound dendrite regression of striatal MSNs. While a single Mn exposure altered the integrity of the dendritic

system and induced significant decrease in spine numbers and total dendritic lengths of MSNs, prolonged Mn exposure led to further reduction in spine numbers and dendritic lengths (Milatovic *et al.*, 2009). In essence, MSNs neurodegeneration could result from loss of spines, removing the pharmacological target for DA-replacement therapy, without overt MSNs death (Stephens *et al.*, 2005; Zaja-Milatovic *et al.*, 2005).

## TOXICITY

Manganese (Mn) is considered to be one of the least toxic of the essential elements (NRC, 2005). There are no reports of acute toxicity of Mn in animals. Therefore, all toxicity studies described here are chronic in nature. A diet can be consumed without any adverse effect when the Mn level is 2000ppm for calves, 3000ppm for sheep, 3000ppm for chickens, 4000ppm for turkeys and 7000ppm for rats. However, decreased growth is observed at 500–3000ppm in swine. These data indicate that pigs are more sensitive to excess Mn than other livestock (NRC, 2005). Mn at a 5000ppm dietary level is lethal to preruminant calves (Puls, 1994). Clinical signs of toxicity include reduced appetite and growth rate, anemia and abdominal discomfort. Excess Mn may be associated with abortions and cystic ovaries. In all domestic animals and poultry, excess dietary Mn is known to cause reduced feed intake, growth rate and lethargy. In dogs, a neurological syndrome of gait

disorders is common and indicative of Mn-induced injury to the extrapyramidal motor system in the brain.

Mn can have a damaging effect on many body organs, including the brain, liver, pancreas and reproductive system. In addition to these well-established neurotoxic effects, Mn has been extensively studied for its reproductive and developmental effects. Evidence obtained from laboratory animals indicates that exposure to high levels of Mn may adversely affect sperm quality (Elbetieha *et al.*, 2001; Ponnappakkam *et al.* 2003a, b), cause decreased testicular weights (Laskey *et al.*, 1982) and impair development of the male reproductive tract. Impaired fertility was observed in male mice exposed to Mn in drinking water for 12 weeks at a daily dose level of 309mg/kg/day, but not at doses  $\leq 154$ mg/kg/day (Elbetieha *et al.*, 2001). Decreased sperm motility and sperm counts were observed in male CD-1 mice after 43 days of exposure to manganese acetate (4.6 to 9.6mg/kg/day). But these doses did not impair the ability of these males to impregnate unexposed females (Ponnappakkam *et al.*, 2003a, b). Szakmary *et al.* (1995) reported that Mn did not result in any reproductive effect in the rabbit when exposed to 11, 22 or 33mg/kg/day on gestation days 6–20. In 13-week dietary studies, no gross or histopathological lesions or organ weight changes were observed in reproductive organs of rats fed up to 618mg Mn/kg/day or mice fed up to 1950mg Mn/kg/day.

Many developmental toxicity studies in animals exposed to Mn have focused on possible effects on reproductive and neurological functions. Animal studies have shown that Mn exposure decreased the growth of reproductive organs (preputial gland, seminal vesicle and testes) (Gray and Laskey, 1980). Testes weights in males were significantly decreased from controls only when Mn was administered in conjunction with an iron-poor diet (Laskey *et al.*, 1982). Studies in neonatal animals have detected structural and neurochemical changes at doses of Mn similar to or slightly above dietary levels (1–10mg Mn/kg/day) (Chandra and Shukla, 1978; Deskin *et al.*, 1980), suggesting that young animals might be more susceptible to Mn than adults. Another study by Dorman *et al.* (2000) also suggested that neonatal rats are at greater risk than adults for Mn-induced neurotoxicity when compared under similar exposure conditions. Their study showed that oral Mn exposure (11 or 22mg/kg/day for 21 days) induced a significant increase in amplitude of the acoustic startle reflex and an increase in striatal DA and 3,4-dihydroxyphenylacetic acid (DOPAC) concentrations in neonates treated with high doses. In a similar study, neonatal rats exposed to Mn (0.31mg Mn/kg/day for 60 days in water) suffered neuronal degeneration and increased brain monoamine oxidase on day 15 and 30 of the study, but did not show any clinical or behavioral signs of neurotoxicity (Chandra and Shukla, 1978). Developmental studies involving the use of laboratory

animals have also detected subtle changes in growth (decreased body weight in animals provided with relatively high doses on Mn). These changes were observed both when the animals were exposed while *in utero* or postpartum. In a developmental rat model of chronic Mn toxicity, administration of Mn in drinking water was associated with increased levels of iron, copper, selenium and calcium in various brain regions. The biochemical mechanisms underlying the interaction between Mn and other minerals are unclear. For further details on Mn-induced reproductive and developmental effects, readers are referred to a recent publication (Milatovic *et al.*, 2011).

Several studies have also addressed gene expression changes in Mn-treated cells and animals and the complex interaction of Mn with other minerals (Baek *et al.*, 2004; HaMai *et al.*, 2006). Mn-induced expression changes were noted in genes involved in inflammation, DNA replication and repair. Recent work in nonhuman primates (Guilarte *et al.*, 2008) detected Mn-induced brain gene expression changes associated mainly with genes affecting apoptosis, protein folding and degradation, inflammation and axonal/vesicular transport.

## DIAGNOSIS

Diagnosis of Mn deficiency and toxicity is based on quantitative determination of Mn in biological specimens (body tissue or fluid). Normal values of Mn in liver and kidney are reported in cattle (2.5–6.0ppm and 1.2–2.0ppm), horses (1.0–6.0ppm and 0.5–2.4ppm), sheep (2.0–4.4ppm and 0.8–2.5ppm), goats (2.0–6.0ppm and 1.0–3.0ppm), pigs (2.30–4.00ppm and 1.30–2.0ppm), dogs (3.0–5.0ppm and 1.2–1.8ppm) and rabbits (1.0–2.0ppm and 2.0–3.0ppm). Mn levels are also reported for blood in cattle (0.07–0.09ppm), sheep (0.02–0.025ppm), dogs (0.02ppm), pigs (0.04ppm) and poultry (0.085–0.091ppm). From human studies it is indicated that neither blood nor urinary Mn levels correlate with any neurological manifestations. Analysis is performed by Flame Atomic Absorption or Furnace Atomic Absorption Spectrometer or Inductively Coupled Plasma (ICP)/ICP-Mass Spectrometer. It is worth mentioning that none of the methods distinguish between different oxidation states of Mn.

## TREATMENT

The very first step in the treatment of Mn poisoning should be to remove the animals from any further exposure by avoiding contaminated feed, water or any other source. Some studies investigating Mn poisoning

suggest that chelation therapy may be considered to reduce the body burden of Mn and to alleviate toxicity symptoms. Chelators bind metal ions in a stable form and the compound chelator plus metal are then excreted by the urinary and/or biliary routes. Ethylene diamine-tetraacetic acid (EDTA) is a polyaminocarboxylic acid that chelates many divalent metals, a property that finds commercial application as a metal sequestrant in food additives. Several studies suggested that EDTA successfully increased Mn excretion in urine and decreased Mn concentration in blood. However, EDTA cannot effectively chelate and remove Mn ions from brain and damaged neurons, and it appears to be of limited therapeutic value for more advanced cases of Mn intoxication.

Since Mn has been shown to catalyze the oxidation of dopamine *in vitro* and the production of dopamine quinone and hydrogen peroxide, it was also suggested that antioxidants may be effective in suppressing Mn toxicity. In addition, interference with oxidation of Mn may affect cellular uptake, elimination of  $Mn^{3+}$  and neurotoxicity. Further investigation of the inhibition of Mn oxidation as a possible mitigation method should be preceded by additional studies to elucidate the role of Mn in its various oxidation states in normal cell metabolism and to determine whether oxidative stress is a primary mechanism for neurotoxicity by Mn exposure.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

Acute manganese (Mn) poisoning is rare in animals, but chronic toxicosis can occur as a result of excess dietary exposure. Mn-induced toxicity can affect several body organs involving multiple mechanism of actions. Several studies suggest that oxidative stress, mitochondrial dysfunction and neuroinflammation are underlying mechanisms in Mn-induced vulnerability of dopaminergic (DAergic) neurons. Mediation of any of these mechanisms and control of alterations in biomarkers of oxidative injury, neuroinflammation and synaptodendritic degeneration may provide a therapeutic strategy for the suppression of dysfunctional DAergic transmission and slowing the neurodegenerative process. In addition, multiple mechanisms of Mn action are not sufficiently known and may vary with environmental factors and susceptibilities, including single nucleotide polymorphisms that may alter Mn homeostasis, Mn transport and metabolism. Therefore, further research is required to investigate the direct link between Mn uptake, distribution, accumulation and its downstream target(s), as well as associated clinical manifestations. Importantly, more conclusive studies on mechanisms associated with the extracellular transport

on Mn, mechanistic effects of Mn at the molecular level and its effects on signal transduction pathways, as well as studies on effective diagnosis and treatment, are needed.

# Mercury

Ramesh C. Gupta

## INTRODUCTION

Mercury (Hg) is a naturally occurring element that exists in several forms, such as elemental (metallic), inorganic and organic. About 80% of the mercury released into the environment is metallic mercury, and it comes from human activities, such as fossil fuel combustion, mining, smelting and from solid waste incineration, as well as from volcanoes and forest fires. Human activities can lead to mercury levels in the soil as much as 200,000 times higher than natural levels. Metallic mercury in a pure form looks like a shiny-white liquid substance at room temperature. It is commonly used in thermometers, barometers, blood pressure measuring devices, button-cell batteries, electric switches, dental fillings (amalgams), etc. Inorganic mercury compounds, or mercury salts, occur when Hg combines with other elements, such as chlorine, sulfur and oxygen. Most of these compounds are white, except mercuric sulfide or cinnabar ore (i.e., red, which turns black after exposure to light). Some mercury compounds are used as fungicides, while others are used for medicinal purposes, e.g., laxatives, deworming agents, antiseptics and disinfectants. When mercury combines with carbon, it is called organic mercury (organomercurials). Methylmercury, ethylmercury and phenylmercury are a few examples. In the environment and mammalian systems, various forms of mercury are interchangeable. For example, inorganic mercury can be methylated to methylmercury and methylmercury can change to inorganic or elemental mercury. Animals at the top of the food chain tend to bioaccumulate methylmercury in their bodies. Therefore, poisoning by mercury is due to consumption

of meat or grain contaminated with mercury. Poisoning can also result from excessive exposure to inorganic and organic mercury compounds from misuse of mercury-containing products. Much of the information presented in this chapter is from experimental studies conducted in laboratory animals and poisoning incidences in humans, animals and wildlife.

## BACKGROUND

Mercury exists naturally in the environment (soil, water and air), and as a result everyone is exposed to very low levels. Aristotle named it "Quicksilver," because it is a silver-colored liquid. Animal poisoning by mercury is rare because of strict federal, state and local regulations. The most common natural forms of mercury found in the environment are metallic mercury, mercury sulfide, mercuric chloride and methylmercury. Methylmercury is of particular concern because it is bioaccumulated and biomagnified in certain edible freshwater and salt-water fish and marine mammals to levels that are many times greater than levels in the surrounding water. As a result, older and predatory fish living in contaminated water build up levels of mercury in their bodies (especially in the liver, kidneys, brain and muscle). Inorganic mercury does not bioaccumulate in the food chain to any extent. Cultivation of edible mushrooms, where waste as compost material with unsafe levels of mercury is used, can also accumulate high levels of mercury (Bressa *et al.*, 1988). The release of methylmercury into an ocean bay (Minamata) in Japan in the 1950s led to a

massive health disaster, and the clinical syndrome was named Minamata Disease (Tsubaki and Krukuyama, 1977; Tsubaki and Takahashi, 1986). Thousands of people were poisoned, and hundreds developed severe brain damage.

The Food and Drug Administration (FDA) estimates that on average most people are exposed to about 50 ng mercury/kg body weight/day in the food they eat. This level is not enough to cause any harmful effects. A large part of this mercury is in the form of methylmercury and the majority of that comes from eating fish. Fish for food consumption are not allowed to have more than 1 ppm mercury. This level is below a level that can be associated with adverse effects. Foods other than fish that may contain higher levels of mercury include wild animals, birds and mammals (bears) that eat large amounts of contaminated fish (ATSDR, 1999). Meat and/or fat from fish, marine mammals, fish-eating wildlife and birds, and mercury-based fungicide-treated grains have the highest mercury levels. Certain species of commercially available saltwater fish, such as shark, swordfish, kingfish and tilefish, can contain high levels of methylmercury. These are all potential sources of mercury poisoning. In horses, mercury toxicity occurs from wound dressings (blisters) when dimethyl sulfoxide (DMSO) is applied simultaneously, because DMSO enhances the absorption of mercury (Schuh *et al.*, 1988).

## TOXICOKINETICS

Absorption of mercury from oral ingestion depends upon the form of mercury. Metallic mercury is maximally absorbed (about 80%) from the lungs, while very little is absorbed from the GI tract. Once mercury enters the circulation, it is rapidly distributed to other tissues, but more so in the kidneys, where it accumulates. Metallic mercury can stay in the body for weeks to months. Due to its high lipophilicity, metallic mercury can readily cross the blood-brain barrier and placental barrier. When metallic mercury enters the brain, it is readily converted to an inorganic divalent mercury (oxidized by the hydrogen peroxidase-catalase pathway), and it gets trapped there for an extended period. The inorganic divalent cation can, in turn, be reduced to metallic mercury. Most of the absorbed metallic mercury excretes in the urine and feces, some amount passes in the milk, and very little in the exhaled air.

Inorganic mercury compounds (e.g., mercurous chloride and mercuric chloride) are absorbed 10–40% from the GI tract upon ingestion, distributed to different organs and mainly accumulate in the kidneys. In an experimental study, female Sprague-Dawley rats given a single dose of

mercuric chloride (7.4 or 9.2 mg Hg/kg, po) showed 12.6 and 18.9 ppm mercury, respectively, in the kidneys when sacrificed 14 days post-exposure (Lecavalier *et al.*, 1994). Trace amounts were also detected in the liver, brain and serum. These compounds do not readily cross the blood-brain barrier or placental barrier. Inorganic mercury excretes in the urine and feces, and only detectable levels pass through the milk.

Organic mercury, such as methylmercury, is readily absorbed from the GI tract (about 90–95%). After ingestion, the distribution to the blood compartment is complete within 30 h, and the blood level accounts for about 7% of the ingested dose. Circulating methylmercury accumulates predominantly in the red cells where it binds to cysteinyl residues (–SH) on the hemoglobin beta-chain, and is then slowly distributed to other tissues, reaching equilibrium with other tissues at ~4 days. The distribution of methylmercury is similar to that of metallic mercury, i.e., a relatively large amount of mercury can accumulate in the brain and fetus (compared to inorganic mercury) because of its ability to penetrate the blood-brain barrier and placental barrier and its conversion in the brain and fetus to the inorganic divalent cation mercury. Organic mercury excretes in the form of inorganic mercury in the feces over a period of several months. Some organic mercury also excretes in the urine and milk.

Depending upon the route of exposure, dose and single versus repeat exposure, toxicokinetics of mercury can follow a one-compartment or two-compartment model. Studies have shown that repeat or continuous exposure to any form of mercury can result in the accumulation of mercury in the body. In vertebrates, mercury tends to accumulate in the liver and kidney, but it also has a high affinity for the brain and endocrine system. Mercury in the brain may persist long after cessation of short- and long-term exposures. Blood levels of mercury are closely related to its levels in the whole body during the first 3 days following administration. Thereafter, the amount of mercury in the blood declines more rapidly than the whole-body burden. Animal studies show disparity in mercury body burden in terms of gender. In general, females are believed to have higher body burdens of methylmercury at given doses than males. Furthermore, in rodents, females accumulate more mercury in the brain, while males accumulate higher levels of mercury in the kidneys.

Evidence suggests that the metabolism of all forms of mercury is similar for humans and animals. Mercury is metabolized through the oxidation-reduction cycle that takes place in intestinal microflora and after absorption in many tissues and in the red blood cells. Elimination rates for methylmercury appear to vary with species, dose, sex and strain. The elimination half-life in the blood of monkeys receiving inorganic and organic

mercury was found to be 26 days (Vahter *et al.*, 1994). In a study of organs from sled dogs fed methylmercury-laden meat and organs from predatory marine animals, the highest concentration of total mercury was found in the mesenteric lymph nodes, followed by liver and kidneys, indicating that the lymphatic system may play an important role in the transport of mercury to target organs (Hansen and Danscher, 1995). The tissue concentrations of mercury observed in this study were found to be age related, and the results suggest that demethylation takes place in all organs, except the skeletal muscles. Demethylation of methylmercury was found to be lower in the brain than in other organs.

## MECHANISM OF ACTION

Toxicities of the different forms of mercury are related, in part, to its differential accumulation in sensitive tissues. This theory is supported by the observation that mercury rapidly accumulates in the kidneys and specific areas of the brain (the two major target organs). High-affinity binding of the divalent cationic mercury to thiol or sulfhydryl groups of proteins is believed to be a major mechanism involved in the toxicity of mercury. As a result, mercury can cause inactivation of various enzymes, structural proteins, transport proteins and alteration of cell membrane permeability by the formation of mercaptides. In addition, mercury may induce one or more of the following effects: increased oxidative stress, mitochondrial dysfunction, changes in heme metabolism, glutathione depletion, increased permeability of the blood-brain barrier and disruption of microtubule formation, protein synthesis, DNA replication, DNA polymerase activity, calcium homeostasis, synaptic transmission and immune response.

The nervous system is especially sensitive to mercury. The degree of damage depends upon the form of mercury and its dose. Metallic mercury at high doses causes irreparable damage to the brain. In many poisoning incidents, permanent damage to the brain occurred by methylmercury. Since inorganic mercury does not readily cross the blood-brain barrier, it is highly unlikely that inorganic mercury may cause any damage to the brain or nerves. Most of the information concerning neurotoxicity in humans following oral exposure to organic mercury comes from reports describing the effects of ingesting contaminated fish or fungicide-treated grains, or meat from animals fed such grains. Studies conducted in experimental animals strongly indicate that organic mercury is a potent neurotoxicant (Kaur *et al.*, 2007; Ceccatelli *et al.*, 2010; Farina *et al.*, 2011).

Evidence suggests that a single dose of mercuric chloride (0.74 mg/kg) caused disruption of the blood-brain

barrier in rats (Chang and Hartman, 1972). These investigators also administered mercuric chloride to rats at the same dose daily for 11 weeks. Within 2 weeks, there were coagulative or lucid changes in cerebellar granule cells and fragmentation, vacuolation and cytoplasmic lesions in the neurons of dorsal root ganglia. Neurological disturbances consisted of severe ataxia and sensory loss.

Neurotoxic effects seen in the Minamata (Japan) and Iraqi poisonings were associated with neuronal degeneration and glial proliferation in the cortical and cerebellar gray matter and basal ganglia (Al-Saleem, 1976). Derangement of basic developmental processes, such as neuronal migration (Matsumoto *et al.*, 1965; Choi *et al.*, 1978) and neuronal cell division (Sager *et al.*, 1983) were also observed. In the brain, Purkinje, basket, stellate and granule cells are severely affected by methylmercury.

Methylmercury selectively inhibits protein synthesis in the brain (reversibly in neurons from the cerebrum and Purkinje cells; and irreversibly in granule cells of the cerebellum), and this effect usually precedes the appearance of clinical signs. This selective action on the brain may be due to the fact that certain cells are susceptible because they cannot repair damage from methylmercury. Cheung and Verity (1985) identified the most sensitive step in the protein synthesis, i.e., peptide elongation can be affected by the high concentrations of mercury, but the first stage of synthesis associated with tRNA may be the most sensitive. Methylmercury inhibits one or more of the amino acyl tRNA synthetase enzymes. Microtubules are essential for cell division (main component of the mitotic spindle), and methylmercury reacts with the SH groups on tubulin monomers, and thereby disrupts the assembly process. The dissociation process continues, and this leads to depolymerization of the tubule. Excess generation of reactive oxygen species (ROS) and inhibition of antioxidant enzyme appear to be the major mechanisms in methylmercury-induced neurotoxicity (Aschner *et al.*, 2007; Franco *et al.*, 2009; Farina *et al.*, 2009). The most recent findings suggest that methylmercury triggers multiple pathways, which may be activated concomitantly, ensuing cell death by apoptosis (Ceccatelli *et al.*, 2010; Farina *et al.*, 2011).

In all forms, mercury accumulates in the kidneys, and thereby causes greater damage to this organ. The kidney damage appears to be dose dependent, and that means recovery can occur if exposure is at low level. Following entry of the mercuric or methylmercuric ion into the proximal tubular epithelial cells via transport across the brush-border or basolateral membrane, mercury interacts with thiol-containing compounds, such as glutathione and metallothionein. This interaction initially produces alterations in membrane permeability to calcium ions and inhibition of mitochondrial function. Subsequently, by unknown signaling mechanisms, mercury induces the

synthesis of glutathione, glutathione-dependent enzymes, metallothionein and several stress proteins. Finally, epithelial cell damage occurs in the kidney as a result of excess free radical formation and lipid peroxidation, and inhibition of antioxidant enzymes.

## TOXICITY

In general, the toxic effects of mercury depend upon the form of mercury, the dose, duration and route of exposure. Mercury, in all forms, has been found to be toxic to both man and animals. There are many similarities in the toxic effects of the various forms of mercury, but there are also differences. Practically, it is organic mercury which is more toxic and often encountered in poisonings following oral ingestion. The major targets of toxicity to inorganic and organic mercury are the kidneys and the CNS, respectively.

Signs and symptoms associated with short-term exposure to metallic mercury may include nausea, vomiting, diarrhea, increase in blood pressure or heart rate, skin rashes and eye irritation.

Inorganic mercury, if swallowed in large quantities, may cause damage to the kidney, and also in the stomach and intestine, including nausea, diarrhea and ulcers. Animal studies revealed that long-term oral exposure to inorganic mercury salts causes kidney damage, an increase in blood pressure and heart rate, and effects on the stomach. Studies also show that nervous system damage occurs after long-term exposure to high levels of inorganic mercury. Short-term, high-level exposure of laboratory animals to inorganic mercury has been shown to affect the developing fetus and may cause termination of the pregnancy.

Laboratory animals exposed to long-term, high levels of methylmercury or phenylmercury showed damage to the kidneys, stomach and large intestine, changes in blood pressure and heart rate, and adverse effects on the developing fetus, sperm and male reproductive organs, as well as increases in the number of spontaneous abortions and stillbirths.

In livestock animals, clinical signs of mercury poisoning vary greatly. In cattle, toxicity signs include ataxia, neuromuscular incoordination and renal failure, followed by convulsions and a moribund state. Average time from ingestion to death is reported to be about 20 days. Ingestion of phenylmercuric acetate may cause sudden death with massive internal hemorrhage, without other signs of toxicity (Puls, 1994). In horses, signs of acute toxicity include severe gastroenteritis and nephritis. In chronic cases, signs may include neurological dysfunction, laminitis, in addition to renal disease which is

characterized by glycosuria, proteinuria, phosphaturia, reduced urine osmolarity, reduced glomerular filtration rate, azotemia and elevated creatinine and blood urea nitrogen. In sheep, the poisoning is characterized by severe neurological symptoms and tetraplegia. Pigs show incoordination, unstable gait, lameness, recumbency and death.

Some of the toxic effects are described below in detail for each organ/system affected by mercury exposure.

### Nervous system

Adverse effects on the nervous system of animals occur at lower doses than do harmful effects to most other systems of the body. This difference indicates that the nervous system is more sensitive to mercury than are other organs in the body. Animal studies also provide evidence of damage to the nervous system from exposure to methylmercury during development, and findings suggest that the effects worsen with age, even after the exposure stops. The reason for this greater susceptibility is that mercury affects processes unique to the developing nervous system, namely cell migration and cell division (Clarkson, 1987).

Both human epidemiology and experimental animal studies indicate that organic mercury is a potent neurotoxicant. Studies suggest that cats and monkeys are more sensitive than rodents to the neurotoxic effects of mercury (especially methylmercury). In several animal species, the major effects that are seen across the studies include motor disturbances, such as ataxia and tremors, as well as signs of sensory dysfunction, such as impaired vision. The predominant pathological feature is degenerative changes in the cerebellum, which is likely to be the mechanism involved in many of the motor dysfunctions. In a chronic study, cats fed tuna contaminated with methylmercury showed degenerative changes in the cerebellum and the cortex (Chang *et al.*, 1974). Neonatal monkeys exposed to methylmercuric chloride at 0.5mg Hg/kg/day for 28–29 days exhibited stumbling, falling, blindness, crying, temper tantrums and coma. Histopathological analysis revealed diffuse degeneration in the cerebral cortex, cerebellum basal ganglia, thalamus, amygdala and lateral geniculate nuclei (Willes *et al.*, 1978).

Rats acutely intoxicated with methylmercury (19.9mg Hg/kg, oral gavage) showed signs of lethargy and ataxia, which was not accompanied by histopathological changes. Symptoms disappeared within 2–3h. Administration of a single dose of methylmercuric chloride (0.8mg Hg/kg) produced blood–brain barrier dysfunction in rats (Chang and Hartman, 1972) similar to that described for inorganic mercury. Neurotoxic signs observed in rats exposed to methylmercury (4mg Hg/kg/day for 8 days) include muscle spasms, gait disturbances, flailing and hind

limb crossing (Inouye and Murakami, 1975; Fuyuta *et al.*, 1978; Magos *et al.*, 1980, 1985). Histopathological examination of the nervous system of affected rats has shown degeneration of cerebellar granule cells and dorsal root ganglia (Magos *et al.*, 1980, 1985) and degenerative changes in peripheral nerves (Fehling *et al.*, 1975; Miyakawa *et al.*, 1976).

Mice exposed to 1.9 or 9.5 mg Hg/kg/day as methylmercury in the drinking water for 28 weeks exhibited degeneration of Purkinje cells and loss of granular cells in the cerebellum (MacDonald and Harbison, 1977). At higher doses, hind limb paralysis was observed. Neuronal degeneration and microgliosis were observed in the corpus striatum, cerebral cortex, thalamus and hypothalamus, accompanied by hind leg weakness, in mice given 1 or 4 mg Hg/kg/day as methylmercuric chloride by gavage for 60 days (Berthoud *et al.*, 1976). In rabbits given 5.5 mg Hg/kg as methylmercuric acetate for 1–4 days, widespread neuronal degenerative changes in cervical ganglia cells, cerebellum and cerebral cortex have been observed without accompanying behavioral changes (Jacobs *et al.*, 1977).

Following inhalation exposure to metallic mercury vapors, the CNS has been found to be the most sensitive organ in guinea pigs, rats and mice. With increasing concentrations of mercury, damage to CNS becomes irreversible. Rabbits appear to be less sensitive to mercury following inhalation exposure.

## Renal system

Mercury, in all forms, has been shown to cause renal toxicity (structural and functional damage) in humans and animal species that are tested. Renal toxicity has been observed in rats (Fisher 344) and mice (B6C3F<sub>1</sub>) following acute, intermediate and chronic exposures to mercuric chloride (Dieter *et al.*, 1992; NTP, 1993). In a 14-day study, male and female rats were exposed by gavage to 0.93–14.8 mg Hg/kg/day as mercuric chloride for 5 days a week. There was a significant increase in the absolute and relative kidney weights of males beginning at the 1.9 mg Hg/kg/day dose level. An increased incidence of tubular necrosis was observed in rats exposed to at least 3.7 mg Hg/kg/day. Severity was dose dependent. In chronic studies, mercuric chloride produced a variety of pathological changes in kidneys (Carmignani *et al.*, 1992; Hultman and Enestrom, 1992; NTP, 1993). Degenerative effects have been found in the kidneys of animals exposed to moderate to high levels of metallic mercury vapors following acute or subacute exposures (Ashe, 1953). Effects ranging from marked cellular degeneration to tissue destruction and widespread necrosis were observed in rabbits exposed to mercury vapor at a concentration of 28.8 mg/m<sup>3</sup> for 2–3 h. In rats, slight degenerative changes (i.e., dense deposits in tubule cells and

lysosomal inclusions) in the renal tubular epithelium were evident following exposure to 3 mg/m<sup>3</sup> mercury vapor for 3 h/day/5 days a week, for 12–42 weeks (Kishi *et al.*, 1978). Low-level, long-term exposure to mercury (0.1 mg/m<sup>3</sup>) has not been found toxic to the kidneys of rats, rabbits and dogs (Ashe, 1953).

## Cardiovascular system

Mercury has been shown to produce adverse effects on the cardiovascular system. A decrease in heart rate was observed in male rats given two gavage doses of 2 mg Hg/kg as methylmercuric chloride (Arito and Takahashi, 1991). An increase in systolic blood pressure was observed in male rats after daily oral gavage doses of 0.4 mg Hg/kg/day as methylmercuric chloride for 3–4 weeks (Wakita, 1987). This effect began approximately 60 days after initiation of exposure and persisted for at least 9 months.

## GI tract

Ingestion of mercuric chloride is highly irritating to the tissues of the GI tract. Inflammation and necrosis of the glandular stomach were observed in mice that were given oral doses of 59 mg/kg as mercuric chloride 5 days a week for 2 weeks (NTP, 1993). In a 2-year gavage study, an increased incidence of forestomach hyperplasia was observed in male rats exposed to 1.9 or 3.7 mg Hg/kg/day as mercuric chloride compared to the control group. Mice showed ulceration of the glandular stomach after 2 years of dietary exposure to methylmercuric chloride at 0.69 mg Hg/kg/day (Mitsumori *et al.*, 1981, 1990).

## Hematopoietic system

In general, acute mercury toxicity does not produce any characteristic hematological changes. In a chronic study conducted in rats, phenylmercuric acetate given in water at a dose of 4.2 mg Hg/kg/day caused decreases in hemoglobin, hematocrit and RBC counts (Solecki *et al.*, 1991). The anemia observed in this study may have been secondary to blood loss associated with the ulcerative lesions in the large intestine. However, methylmercuric chloride at a low dose (0.1 mg Hg/kg/day for 2 years) given in the diet for 2 years caused no changes in hematological parameters (Verschuuren *et al.*, 1976).

## Other effects

Mercury has been found to have the potential for inducing genotoxicity (Ghosh *et al.*, 1991), carcinogenicity

(Solecki *et al.*, 1991; NTP, 1993), immunotoxicity (Thuvander *et al.*, 1996), and endocrine, reproductive and developmental toxicity (Fuyuta *et al.*, 1979; Castoldi *et al.*, 2008; Liang *et al.*, 2009; Tan *et al.*, 2009; Vitalone *et al.*, 2010; Ni *et al.*, 2011).

## Diagnosis

Presently there are reliable and accurate ways to measure mercury levels in the body, using atomic absorption spectrometer and inductively coupled plasma (ICP) or ICP-mass spectrometer (ICP-MS). Mercury analysis is usually performed on blood, urine, milk, hair, nail, liver and kidney. Mercury in urine is determined to test for exposure to metallic or inorganic mercury, while whole blood or hair values are used to determine exposure to methylmercury. Mercury levels in the blood provide more useful information after recent exposures than after long-term exposures. Levels found in blood, urine and hair may be used together to predict possible health effects that may be caused by the different forms of mercury. The kidney is an ideal specimen for mercury analysis from dead animals.

## TREATMENT

Activated charcoal (1–3g/kg body weight, po) is very effective in reducing further absorption of mercury from the GI tract. Specific treatment of mercury poisoning rests with the use of chelators, along with protein solutions to bind and neutralize mercury compounds. The use of a particular chelator is dependent upon the type of mercury exposure. Among several chelators, dimercaprol (BAL, 3mg/kg, im) has been found to be the most effective against mercury poisoning. However, chelation releases mercury from soft tissues which can be redistributed to the brain. Oral administration of sodium thiosulfate (1g/kg) can assist in eliminating mercury. Animal studies suggest that antioxidants (particularly vitamin E) may be useful for decreasing the toxicity of mercury. Improved chelation and drug therapies for treating acute and chronic mercury poisonings are greatly needed.

## CONCLUSIONS

Toxicity by mercury depends upon the form of mercury, dose, duration and route of exposure. Organic mercury tends to bioaccumulate in the higher food chain, and as a result the maximum concentrations are found in the meat of fish, marine mammals and fish-eating birds and

wildlife. Methylmercury is the most toxic among the mercury species because of its volatility and its ability to pass through biological membranes such as the blood–brain barrier and the placental barrier. The nervous system and kidneys are the two major target organs. Not all forms of mercury cross the blood–brain barrier (e.g., inorganic mercury), but in all forms it accumulates in the kidney and thereby causes damage to this organ. Chelation therapy appears to be the best treatment. Oral administration of activated charcoal is very effective in reducing the further absorption of mercury from the GI tract.

## ACKNOWLEDGMENT

I would like to thank Mrs. Robin B. Doss for her assistance in the preparation of this chapter.

# Molybdenum

Jeffery O. Hall

## INTRODUCTION

Molybdenum (Mo) is an essential nutrient in plants and animals. Thorough reviews on Mo have been published (Dick, 1956; Underwood, 1977; Ward, 1978; Friberg and Lener, 1986; Mills and Davis, 1987; Rajagopalan, 1988; Nielsen, 1996; Johnson, 1997; NRC, 2006). In plants and microbes, reduction of nitrate to nitrite and nitrogen fixation requires Mo (Williams and daSilva, 2002). Higher animals require Mo for oxygen transfer reactions of aldehyde oxidase, sulfite oxidase and xanthine oxidase, where Mo is bound to a pterin nucleus (Johnson *et al.*, 1980). Although dietary clinical deficiencies have not been reported under natural conditions (Mills and Davis, 1987), deficiency has been produced in animals fed purified Mo deficient diets (Mills and Bremner, 1980; Anke *et al.*, 1985). Functional Mo deficiency has been caused by genetic disorders in humans (Reiss, 2000) and competitive replacement of tungsten for Mo in enzymes (Nell *et al.*, 1980). And, iatrogenic Mo deficiency, resulting in aberrant sulfur-containing amino acid metabolism, has been reported following prolonged total parenteral nutrition (Abumrad *et al.*, 1981).

Mo toxicity is intricately tied to interactions with copper and sulfur. Predominant manifestations of Mo poisoning are associated with secondary copper deficiency, but not all clinical symptoms are alleviated by copper supplementation. The copper-sulfur-Mo interactions are complex and vary greatly in degree of severity among species.

## BACKGROUND

Mo is a transition metal within group VI of the periodic table. It has an atomic number of 42, an atomic weight of 95.95 and has seven different naturally occurring atomic masses from 92 to 100 (Rosman and Taylor, 1998). Mo can occur in a variety of oxidation states that range from (-II) to (VI) (IMOA, 2006), but valence states IV, V and VI are the most common in biological systems (Johnson, 1997). Mo is utilized in the production of oxidation catalysts, pigments, corrosion-resistant steel, smoke suppressants, lubricants, fertilizers and metal alloys. Although uniformly found in nature, the United States has the greatest producible Mo reserves.

Mo is commonly found in low concentrations in most dietary constituents (Rajagopalan, 1988), but excess intake can occur from plants grown on soils naturally high in Mo or from areas contaminated by mining or smelting operations. Naturally high soil and forage molybdenum concentrations have been reported in very localized areas of several states in the western United States, as well as Canada, England, Australia and New Zealand, but likely occurs in other countries as well. In addition, high molybdenum forages have been identified from contaminated areas associated with mining and industrial operations (King *et al.*, 1984). Daily dietary requirements for all species are such that requirements are met, even with low intake.

## PHARMACOKINETICS/ TOXICOKINETICS

### Absorption

Mo absorption differs between monogastrics and ruminants. In monogastrics, Mo absorption occurs from the stomach throughout the intestinal tract (Bell *et al.*, 1964; Miller *et al.*, 1972; Nielsen, 1996). In contrast, ruminant absorption occurs in the intestinal tract, as an extensive delay in peak blood concentration would indicate that rumen absorption does not occur. This mucosal absorption is via an active carrier-mediated process that is also utilized by sulfate (Mason and Cardin, 1977). Absorption is quite efficient, being from 40 to 90% (Friberg and Lener, 1986; Turnlund *et al.*, 1995). But, Mo absorption does not appear to be regulated at the point of mucosal absorption, as increasing Mo concentrations presented to the mucosa result in concomitant increased absorption (Miller *et al.*, 1972; Turnlund *et al.*, 1995).

Dietary constituents can limit Mo absorption. Dietary sulfate present at the point of absorption can competitively inhibit Mo uptake (Mason and Cardin, 1977). Furthermore, in the presence of sulfur/sulfates, the reductive rumen metabolism results in di-, tri- and tetra-thiomolybdates, which can then bind copper and form a non-absorbable cupric thiomolybdate complex (Dick, 1956; Price *et al.*, 1987; Gooneratne *et al.*, 1989).

### Distribution

Mo is widely distributed in tissues, but has highest concentrations in the liver, kidney and bone (Schroeder *et al.*, 1970; Friberg and Lener, 1986). In light of the essential nature of Mo, it is somewhat unusual that very little tissue retention/reserve is maintained. Post-absorptive circulation occurs by transport bound to the red blood cell proteins or as free ionic molybdate (Allway *et al.*, 1968; Versieck *et al.*, 1981). But, absorbed or systemically produced thiomolybdates can bind copper and result in circulating copper–thiomolybdate complexes which are not biologically available for tissue utilization.

### Elimination

Mo is eliminated from the body fairly rapidly, with little, and only short-term, tissue retention. Although urinary is the primary route of elimination, biliary elimination also occurs (Friberg and Lener, 1986; Vyskocil and Viau, 1999; NRC, 2006) and likely is the primary route of elimination in ruminants (Grace and Suttle, 1979; Pott *et al.*, 1999). Urinary elimination is concentration dependent,

resulting in relatively rapid elimination even with very large exposures. In lactating animals, Mo is excreted in the milk with content being dependent on the concentration being ingested (Archibald, 1951; Anke *et al.*, 1985). Thus, exposure can be approximated by analysis of urine or milk for Mo content across time and extrapolating back to the time of exposure (Lesperance *et al.*, 1985). Just as sulfate can inhibit the absorption of Mo, it can also compete for reabsorption sites in the renal tubules and enhance the rate of elimination (Friberg and Lener, 1986).

## MECHANISM OF ACTION

The mechanism by which Mo is active in biologic systems is through its redox activity in functional molybdo-enzymes (Mills and Davis, 1987). The readily changeable oxidation states of Mo lend it to functional utilization in these types of reactions.

The primary mechanisms by which Mo is toxic are directly tied to its interactions with sulfur and copper. These interactions result in functional or overt copper deficiency. But, these interactions differ significantly among species, with ruminants being much more susceptible than monogastrics. The reducing environment of the rumen converts sulfate or sulfur from sulfur-containing amino acids to sulfide, which then forms mono-, di-, tri- and tetra-thiomolybdates (Price *et al.*, 1987; Spears, 2003). Thiomolybdates binding of copper in the digestive tract prevents absorption of ingested copper, while systemic binding renders it non-bioavailable for tissue utilization (Gooneratne *et al.*, 1989; Suttle, 1991). These cupric-thiomolybdate complexes also result in enhanced copper excretion (Howell and Gooneratne, 1987). Price *et al.* (1987) found that the ruminal binding was predominantly via tri- and tetra-thiomolybdates, while systemic effects were predominantly via di- and tri-thiomolybdates. In practical means, the thiomolybdates serve as effective chelators of copper, preventing copper absorption and depleting functional body stores. As the ruminal microbial populations can differ significantly among ruminant species, the relative sensitivity among species could be related to the overall conversion to thiomolybdates or the relative abundances of the mono-, di-, tri- and tetra-thiomolybdates produced.

Most of the clinical syndromes of Mo poisoning can be tied to deficiencies in copper-containing enzyme systems (NRC, 2006). Although most clinical effects of Mo poisoning are reversed by supplementation of copper, Mo may have some direct toxic effects. It is possible that permanent tissue damage, caused by severe copper depletion, results in non-response to copper supplementation in clinically affected animals. The exact mechanisms of

non-copper responsive toxic effects of Mo are poorly defined or investigated, but it has been observed that high Mo concentrations can inhibit the *in vivo* activity of biological enzymes, such as succinic acid oxidase, sulfide oxidase, glutaminase, cholinesterase and cytochrome oxidase (Venugopal and Luckey, 1978).

## TOXICITY

Both acute and chronic toxicity of Mo varies greatly among species. Monogastric animals are much less sensitive than ruminants, due to the rumen metabolism of sulfur and formation of thiomolybdates. The relative tolerance to Mo has been ranked: horses > pigs > rats > rabbits > guinea pigs > sheep > cattle (Venugopal and Luckey, 1978), but more recent literature suggests horses may be more sensitive (Ladefoged and Sturup, 1995). In total, the toxicity of Mo needs to be evaluated with consideration of dietary sulfur/sulfates and copper. This is with knowledge that sulfates competitively inhibit uptake from the intestinal tract, but in ruminants results in the formation of thiomolybdates which will enhance the toxic effects on copper status.

Natural toxic effects of Mo are primarily via ingestion, but toxicity has been demonstrated by both inhalation and injection in laboratory rodents. Intraperitoneal LD<sub>50</sub> of Mo in rats ranges from 99 to 22.8 mg/kg body weight (Venugopal and Luckey, 1978), with similar lethal doses in mice and guinea pigs. Chronic inflammatory lesions and hyaline degeneration within the respiratory tree was induced by Mo trioxide exposure of 10–100 mg/m<sup>3</sup> 6 h per day, 5 days a week (Chan *et al.*, 1998). Increased incidence of respiratory adenomas was also seen in the rats and mice.

Concentrations of Mo required to produce acute poisoning orally differ significantly among species. For cats, rabbits and guinea pigs, the oral LD<sub>100</sub> for Mo is 1310, 1020 and 1200 mg/kg body weight, while the oral LD<sub>50</sub> for rats is 125–370 mg/kg body weight (Venugopal and Luckey, 1978). Little acute toxicity data are available for domestic animals, but cattle have been acutely poisoned with feed containing 7400 mg Mo/kg diet (group average intake of 31 mg Mo/kg body weight/day) and Mo was acutely lethal in sheep at 132–137 mg Mo/kg body weight/day for 2–3 days (Swan *et al.*, 1998).

Clinical signs and pathologic lesions in acutely poisoned animals differ from those seen with more chronic poisonings. Acutely poisoned cattle and sheep developed feed withdrawal, lethargy, weakness, hind limb ataxia that progressed to the front limbs and recumbency (Swan *et al.*, 1998). The cattle also had profuse salivation, ocular discharge and mucoid feces. Hydropic hepatocellular degeneration/necrosis and hydropic degeneration/

necrosis of the proximal and distal renal tubules was observed in both cattle and sheep.

Subacute to chronic toxicity of Mo is just as species dependent as acute poisoning. Oral lethal doses of Mo administered chronically to laboratory animals (rats, mice, guinea pigs and rabbits) range from 60 to 333 mg Mo/kg body weight/day, while cattle are poisoned with as little as 3 mg Mo/kg body weight/day (NRC, 2006). Literature reports of toxic dietary Mo content range from 10 to 1200 ppm for rats, 300 to 8000 ppm for poultry, 200 to 4000 ppm for rabbits, 1000 to 8000 ppm for Guinea pigs, 2.5 to 20 ppm for sheep and 2 to 400 ppm for cattle (Pitt, 1976). Ruminants commonly succumb to molybdenosis when Mo intake is greater than 20 ppm in the diet. However, due to the intrinsic nature of the Mo–copper–sulfur interactions, chronic Mo poisoning in ruminants can be divided into three classes: dietary Mo greater than 20 ppm, low Cu:Mo ratio (<2:1) and high dietary sulfur with normal copper and Mo (Ward, 1978). The desired Cu:Mo ratio in ruminants is between 6:1 and 10:1 (Thompson *et al.*, 1991). Thus, Mo toxicosis can occur at much low concentrations in association with copper deficient forages than those with diets adequate in copper.

Most clinical signs of chronic Mo poisoning are associated with induced copper deficiency. Commonly, the first recognized clinical sign of chronic Mo poisoning is severe diarrhea (Dick, 1956; Pitt, 1976; Underwood, 1977; Ward, 1978; Friberg and Lener, 1986; Mills and Davis, 1987; Rajagopalan, 1988; Nielsen, 1996; Johnson, 1997; Coppock and Dziwenka, 2004; NRC, 2006). “Teart” is used to refer to soil or plants that contain unusually high amounts of Mo, thus the term teart scours is commonly used to describe the diarrhea associated with excessive Mo intake. Although the exact mechanism is not well defined, copper supplementation alleviates this clinical sign. Other common clinical signs of chronic Mo poisoning include poor body weight gain, weight loss, anemia, decreased milk production, achromotrichia, alopecia, limb deformities, bone fractures, periostosis, lameness, lack of libido and ataxia. Abortions have been reported in horses.

Pathologic alterations of chronic Mo poisoning are not specifically diagnostic. These lesions are secondary to induced copper deficiency and include emaciation, periostosis and epiphyseal plate growth abnormalities. Because of the nature of chronic Mo poisoning, primary copper deficiency must always be ruled out when these lesions are identified.

## TREATMENT

The two primary mechanisms of treating Mo toxicosis involve removal from the source of high Mo and

copper supplementation, but administration of sulfate to monogastrics will enhance elimination rates. Administration of sulfates to ruminants would not be recommended, as ruminal reduction to sulfide could potentially result in greater thiomolybdate concentrations and worsen the clinical disease. With rapid clearance from the body, removal from the high Mo source will quickly remove excess Mo from the body. However, permanent damage may be present that results in sustained animal deaths for weeks to months post-exposure (Swan *et al.*, 1998). Supplementation of copper in Mo-poisoned animals must be done with care, especially in sheep, to prevent excessive copper accumulation and subsequent copper toxicosis.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

The known mechanisms of Mo poisoning are a complex interaction with sulfur and copper that differ significantly across animal species. But, some clinical effects of Mo poisoning have not been related to absolute or functional copper deficits, as replenishment of copper does not result in cessation of clinical effects. These clinical effects of Mo poisoning need further investigation to delineate the mechanism by which Mo produces adverse animal health.

# Selenium

Jeffery O. Hall

## INTRODUCTION

Selenium is an essential nutrient that has a relatively narrow window between ingested amounts that result in deficiencies and those that cause toxicoses. Historically, occurrences of livestock disease that mimic clinical presentation of chronic selenium poisoning were recorded in the 13th century (Martin, 1973). Marco Polo wrote of such cases in western China in 1295. In 1560, Father Simon Pedro described human cases of presumably chronic selenosis in Columbia (Benavides and Mojica, 1965). The first documented record of selenium poisoning in livestock was reported in 1860 by a U.S. Army surgeon (Martin, 1973). T.W. Madison described a fatal disease of horses that grazed near Fort Randall, South Dakota. It also has been speculated that the horse illness that slowed General Custer's Cavalry relief may have been due to selenium, but chronic selenosis generally takes weeks to develop.

Selenium deficiency had been historically linked to a variety of clinical effects. Since 1949, vitamin E, cysteine and a "factor 3" were known to protect rats from fatal liver necrosis (Schwarz and Foltz, 1957). When rats were fed torula, a brewer's yeast, they developed liver necrosis that could be avoided by use of baker's yeast (*Saccharomyces* sp.). It was postulated that an essential nutrient, "factor 3," was deficient in torula. After much research, the active, preventive element present in "factor 3" was identified as selenium. Several metabolic diseases of previously unknown origin were later found to relate to selenium deficiency, including "white muscle disease" (WMD) in calves and lambs (Muth *et al.*, 1958; Godwin and Fraser, 1966), hepatitis dietetica in pigs (Eggert *et al.*, 1957), exudative diathesis in poultry

(Patterson *et al.*, 1957) and pancreatic degeneration in poultry (Thompson and Scott, 1969).

Since its first discovery as an essential nutrient, selenium has been found to act in numerous body systems. In 1973, Se was identified as an essential component of glutathione peroxidase (GSH) enzyme (Flohe *et al.*, 1973; Rotruck *et al.*, 1973). Selenium was shown to be essential in humans when added dietary selenium prevented a cardiomyopathy known as "Keshan disease" (Chen, 1986). Selenium supplementation may also be protective against certain types of cancer (Combs, 1997), cardiovascular disease (Duthie *et al.*, 1989) and viral infections (Schrauzer, 1994; Levander, 2000). Because of the essential nature of selenium, poisoning cases from both natural plant accumulations of selenium and nutritional overdoses are encountered.

The identified essential functions of selenium are still increasing. The most notable is GSH, where selenocysteine is a required component of the enzyme system (Brown and Arthur, 2001). Reduced GSH is the primary physiologic first defense against free radical damage to tissues, helping to maintain functional membrane integrity. Several subclasses of GSH are now recognized (Cohen and Avissar, 1994; Sunde, 1994). To date over 30 selenoproteins have been identified, many of which have vital enzymatic functions (Tiwary, 2004). Thioredoxin reductase I, II and III (Brown and Arthur, 2001), 5' triiodothyronine deiodinase (Arthur and Beckett, 1994) and "selenoprotein" are also selenium dependent. In addition, selenium plays several roles in normal immune function, reproductive function, hepatic biotransformation reactions, neurotransmitter turnover and anti-carcinogenic functions.

## BACKGROUND

Selenium is a member of the non-metallic elements within group VIA of the periodic table. It has an atomic number of 34, an atomic weight of 78.96, and has six different naturally occurring stable isotopic masses from 74 to 82 (Rosman and Taylor, 1997). Selenium has four natural oxidation states:  $-2$  (selenides),  $0$  (elemental),  $+4$  (selenites) and  $+6$  (selenates) (Barceloux, 1999). Selenium was first identified in 1817 by Jons Jakob Berzelius, a Swedish chemist, who investigated worker illnesses in a sulfuric acid plant at Gripsholm, Sweden (Fredga, 1972). He named this element after "Selene," the green moon goddess.

Many areas within the Northern Great Plains of the United States, such as the Dakotas, Wyoming, Montana, Nebraska and Kansas, have high soil selenium content (4–5 ppm Selenium or more), resulting in high plant uptake and subsequent Se toxicosis in herbivores (Rosenfeld and Beath, 1964). High soil selenium also occurs in alkaline soils of some localities in Algeria, Argentina, Australia, Bulgaria, Canada, China, Columbia, Ireland, Israel, Mexico, Morocco, New Zealand, South Africa, the former Soviet Union, Spain and Venezuela (NRC, 1983). However, total soil selenium is not the best indicator of potential selenium poisonings, as Hawaii and Puerto Rico have areas of high soil selenium that is not available to the plants due to the acidic soil types, which result in lowered water soluble, bioavailable selenium for plant uptake (Lakin, 1961).

Inorganic forms of selenium are the primary form in soil. Only the water soluble forms are readily available for plant uptake, with the greatest absorption being in the form of selenate via the sulfate transporter. Elemental selenium and precipitated metal-selenides are not bioavailable for plant uptake. Some "indicator plants" or "obligatory selenium accumulator plants" can accumulate several thousand ppm selenium and are often found in selenium-rich areas, since they require high selenium for growth (Rosenfeld and Beath, 1964). These plants include genera such as *Astragalus* (milk vetch), *Xylorhiza*, *Machaeranthera* (woody aster), *Haplopappus* (golden weed) – formerly known as *Oenopsis* and *Stanleya* (prince's plume). Selenium content as high as 14,990 ppm have been reported for a sample of *Astragalus racemosus* (Beath, 1937). Although these indicator plants have poor palatability, during times of limited forage, they are eaten. Secondary or facultative accumulating plants can survive with high selenium content, but do not require it for growth. These plants are often more palatable than the indicator plants and include *Aster*, *Atriplex* (salt bush), *Castilleja* (paintbrush), *Gutierrezia* (snakeweed), *Grindelia* (gumweeds), *Sideranthus* (ironweed), *Eurotia* (winter fat), *Mentzelia*, *Machaeranthera* and *Gyria* sp., as well as some crop plants such as western wheat grass, barley, wheat, alfalfa, onions and Swiss chard (Beath *et al.*, 1935; Williams and Byers, 1936).

Most of the selenium in non-indicator plants and other biological matrices is in an organic form, but small amounts of inorganic selenate and selenite can also be present. The vast majority of plant selenium, especially in non-indicator plants, is in the form of selenomethionine, but selenocysteine and a variety of other seleno-amino acid derivatives can also be found (Peterson and Butler, 1962; Olson *et al.*, 1970; Whanger, 2002). In contrast, the majority of selenium in indicator plants, such as *Astragalus*, is a water soluble Se-methyl-selenocysteine (Shrift, 1973), but can also have selenocystathionine (Lewis, 1976). Garlic was found to contain significant selenomethionine, as well as glutamyl-Se-methyl-selenocysteine and possibly gamma-glutamyl-selenomethionine (Kotrebai *et al.*, 1999). The non-protein associated selenium compounds may be a protective mechanism of the plants to prevent excessive replacement of methionine or other sulfur-containing amino acids with seleno-amino acids in plant proteins resulting in loss of disulfide bonds, misfolding and altered protein properties (Peterson and Butler, 1962). Some microbial populations, as well as plants, can reduce selenium to volatile chemical forms (Shrift, 1973).

## PHARMACOKINETICS/ TOXICOKINETICS

### Absorption

The majority of ingested selenium compounds are absorbed from the duodenum, with lesser amounts in the jejunum and ileum (Wright and Bell, 1966; Whanger *et al.*, 1976). Little to no absorption reportedly occurs from the stomach and rumen. However, one report suggests that minimal absorption of selenomethionine occurs through the rumen wall and into the blood (Hidiroglou and Jenkins, 1973).

The chemical form of selenium greatly impacts the overall absorption. Selenite absorption is via passive diffusion through the brush border membranes (Vendeland *et al.*, 1992, 1994). In contrast, selenate has little affinity for the brush-border membranes. Selenate is absorbed via a sodium co-transport system that is also utilized by sulfate (Wolffram *et al.*, 1988). Selenium in the form of seleno-amino acids, selenomethionine and selenocysteine are absorbed through active amino acid transport mechanisms and are more bioavailable than selenite or selenate (McConnell and Cho, 1967; Ammerman and Miller, 1974; Vendeland *et al.*, 1994). The selenium status did not affect overall absorption, indicating that absorption was not under homeostatic regulation.

In monogastrics, the relative selenium absorption is greater than in ruminants, ranging from 45 to 95%

(Thomson and Stewart, 1974; Furchner *et al.*, 1975; Bopp *et al.*, 1982). And organic forms of selenium are better absorbed (Robinson *et al.*, 1978). In ruminants, the relative absorption ranges from 29 to 50% (Wright and Bell, 1966; Suttle and Jones, 1989). The decreased absorption in ruminants is due to microbial reduction of selenium forms in the rumen to selenides and elemental selenium which are not bioavailable (Cousins and Cairney, 1961; Whanger *et al.*, 1968; Peter *et al.*, 1982). This reduction in bioavailability is generally exacerbated by high carbohydrate diets, but can be altered by differing rumen microbial populations (Hudman and Glenn, 1984; Koenig *et al.*, 1997). Some rumen microbes more efficiently reduce selenium, while others effectively incorporate it into selenium-containing amino acids. The incorporation of selenium into microbial proteins, as well as systemic absorption, can be competitively inhibited by natural methionine and cysteine (Serra *et al.*, 1996).

## Distribution

Tissue distribution is dependent on the chemical form of selenium absorbed. Selenium is generally utilized for synthesis of selenoproteins, incorporated into tissue proteins or eliminated. Selenomethionine can be non-specifically incorporated into tissue proteins in place of methionine (Awadeh *et al.*, 1998), but selenocysteine is not (Burk *et al.*, 2001), with highest incorporation occurring in tissues with high rates of protein synthesis (Hansson and Jacobsson, 1966). The non-specific incorporation of selenomethionine effectively serves as a pool of selenium reserve with a long biological half-life (Schroeder and Mitchener, 1972a). Highest total selenium content is typically found in the kidney and liver, with lesser amounts in all other tissues (Muth *et al.*, 1967; Levander, 1987; Echevarria *et al.*, 1988; Davidson and Kennedy, 1993). Both specific and non-specific selenium incorporation into proteins was greater in selenium-deficient animals.

Time to peak tissue concentrations is tissue dependent. Peak selenium content of blood, liver, muscle, kidney, spleen and lung was reached within 24h after an injection of  $^{75}\text{Se}$  as selenite (Muth *et al.*, 1967). In contrast, brain, thymus and reproductive organs do not reach maximal content until much later (Brown and Burk, 1973; McConnell *et al.*, 1979; Smith *et al.*, 1979; Behne *et al.*, 1988).

Selenium is efficiently transferred across the placenta into feti during gestation. The overall maternal selenium content is positively correlated with fetal and newborn selenium status (McConnell and Roth, 1964). Although they get the vast majority of selenium *in utero*, newborns do get minimal amounts of selenium from milk, with much higher content in colostrums than in milk later in lactation.

## Metabolism

Selenite is metabolized in red blood cells to hydrogen selenide (Gasiewicz and Smith, 1978). Sequential methylation reactions result in the formation of monomethylselenide, dimethylselenide and trimethylselenide (Kajander *et al.*, 1991; Itoh and Suzuki, 1997). These reactions utilize *S*-adenosylmethionine for methyl groups which are transferred by methyltransferases (Kajander *et al.*, 1991). These sequential reactions can deplete available *S*-adenosylmethionine, which would limit the degree of methylation. In rats given selenomethionine, trimethylselenide occurred in the urine more rapidly than in rats given sodium selenite or selenocysteine, indicating that selenomethionine may be converted to methylselenol which is easily further methylated.

Selenomethionine is metabolized by demethylation to selenocysteine. This set of pathways is similar to the metabolism of methionine. The selenocysteine is then metabolized by selenocysteine-beta-lyase in the liver and kidney to alanine and selenide (Soda *et al.*, 1987).

## Elimination

Selenium is primarily excreted in the urine and feces, but the form and extent of elimination by different routes are dose and species dependent. In monogastric animals, urinary elimination predominates, irrespective of the route of exposure (Leng *et al.*, 2000), with less than 10% recovered in feces (Burk *et al.*, 1972). Some literature suggests that urinary eliminated selenium is predominantly metabolites of selenium, with trimethylselenide predominating at higher doses (McConnell and Roth, 1966; Palmer *et al.*, 1969; Zeisel *et al.*, 1987; Itoh and Suzuki, 1997), but monomethylselenide is more abundant at lower doses. Human elimination is tri-exponential for selenite and selenomethionine (Alexander *et al.*, 1987). The terminal elimination phase was 8–20 and 230 days for selenite and selenomethionine, respectively. Overall selenium retention and maintenance of adequate selenoenzymes are for a much longer time period in animals supplemented with selenomethionine than selenite. Elimination rate is dose dependent, with half-lives of 19.5 and 1.2 days with selenite of 0.1 and 1.0ppm in the diet, respectively (Burk *et al.*, 1972). Due to non-specific protein incorporation of selenomethionine, urinary and fecal recovery after dosing was less than 30% of that for equal selenium doses from selenite or selenate (Thomson, 1998).

The literature suggests that the predominant selenium elimination in ruminants is fecal when ingested, but urinary with parenteral administration or in non-ruminating young animals. This is actually an error in terminology, as the fecal loss of selenium is primarily in the forms of

elemental selenium and precipitated selenides from ruminal reduction (Langlands *et al.*, 1986). Thus, this selenium is just non-absorbed material and not truly being eliminated from the central compartment. However, a small amount of metabolized selenium excesses is excreted in the bile (Cousins and Cairney, 1961). The selenium metabolites eliminated in the urine follow a similar pattern to that seen with monogastrics. Urinary elimination is predominant with parenteral administrations and in non-ruminating young animals (NRC, 1983).

Renal selenium elimination is dependent of glomerular filtration and degree of reabsorption. Increasing renal fluid absorption did not increase the selenium content in urine, indicating a tubular reabsorptive process (Oster and Prellwitz, 1990). Thus, dehydration or renal insufficiency would decrease rates of elimination. Excretion and renal clearance rates correlate with creatinine, indicating glomerular filtration is the mechanism of elimination.

Some selenium is eliminated via respired air, but the relative importance of this route is dose dependent. At normal intake, only about 10% or less is eliminated from the respiratory tract (Burk *et al.*, 1972), but as dose increases the percent eliminated in respired air increases (Jacobsson, 1966; McConnell and Roth, 1966). Dimethylselenide and dimethyldiselenide are the predominant forms eliminated in respired air at toxic doses. Dimethylselenide predominates when mice were dosed with selenite or selenocysteine, while dimethyldiselenide is most abundant when rats were dosed with selenomethionine. Respiratory elimination is primary when renal elimination thresholds are maximized, which results in most respiratory elimination occurring in a short-time period soon after exposure to toxic doses (McConnell and Roth, 1966; Tiwary *et al.*, 2005).

## MECHANISM OF ACTION

Although much research has been conducted with regard to selenium poisoning, the exact mechanism of the toxic effects in the body are still not clear. With acute poisoning, one theory is the depletion of intermediate substrates, such as glutathione and S-adenosylmethionine, which disturbs their respective enzyme activities (Vernie *et al.*, 1978). Another potentially interactive theory is the production of free radicals by reaction of selenium with thiols, causing subsequent oxidative tissue damage (Hoffman, 2002; Kaur *et al.*, 2003; Balogh *et al.*, 2004). A third theory is the incorporation of selenium compounds in place of sulfur, such as in proteins, in which it disrupts normal cellular functions (Raisbeck, 2000). This is an especially likely mechanism for the hair and hoof lesions of chronic selenium poisoning, with the loss

of disulfide bridges which provides structural integrity to these tissues. This would also apply to inhibition of DNA methylation by S-adenosylmethionine or indirect inhibition by increased S-adenosyl homocysteine content (Hoffman, 1977). And, it is possible that each of these proposed mechanisms is valid with respect to specific chemical forms of selenium. It has been observed that tissues requiring selenium to prevent deficiency-associated disease (immune system, reproductive organs and muscular tissues) also tend to accumulate more selenium with excess exposure and are tissues of toxic effects.

## TOXICITY

Selenium poisoning cases generally fall into three types of exposure history. The first is from ingestion of selenium in plants that have accumulated it from naturally seleniferous soils. The second is from accidental overdoses by injection or errors in feed mixing. And the third is from environmental contamination, which often results in exposure from plant accumulation and or contaminated waters. With each of these types of poisonings, one may see acute, subacute or chronic selenium poisoning, depending upon the daily exposure rate. However, one must understand that an animal's age plays a role in susceptibility to selenium poisoning, as young animals are less tolerant than adults (Raisbeck, 2000).

Doses for acute selenium toxicosis vary significantly across species, but also by route of exposure, with injectable routes of exposure being more toxic than oral. Acute oral selenium poisoning occurs with sudden exposure ranging from 2.2mg/kg (Rosenfeld and Beath, 1964) to greater than 20mg/kg body weight (Miller and Williams, 1940; Mahan and Moxon, 1984) across species. The relative oral acute toxicity of selenium containing compounds is dependent on their solubility, with poorly soluble selenides and elemental selenium being much less toxic than soluble selenates, selenites and organic selenium (NRC, 2005). Minimum lethal dose for rabbits, rats, dogs and cats is 1.5–3mg/kg body weight (NRC, 1983). The LD<sub>50</sub> for oral selenite has been estimated to be 1.9–8.3mg/kg body weight in ruminants (Grace, 1994), but other references suggest it to be 9–20mg/kg body weight (Puls, 1994). In poultry, the acute oral LD<sub>50</sub> of selenium is 33mg/kg body weight. Injectable selenium is more acutely toxic than oral, with intramuscular LD<sub>50</sub> of 0.5mg/kg in lambs (Caravaggi *et al.*, 1970). Subcutaneous LD<sub>50</sub> of selenium is 1 mg/kg in lambs and 1.9mg/kg in adult cattle (Grace, 1994). In 2009, 21 horses from Venezuela that were in Florida for an international polo match died from selenium overdose (Florida, 2009; Desta *et al.*, 2011). The selenium was misformulated in

a compounded intravenous vitamin-mineral product, but the exact amount of the overdose has yet to be published. The horses developed clinical signs within hours of the administration and died within 3 to 18 hours.

Clinical manifestation of acute selenium poisoning begins as early as 8–10h, but can be delayed for up to 36h (Franke and Moxon, 1936; NRC, 1983; Raisbeck, 2000; Tiwary *et al.*, 2006). Early in the clinical syndrome, one can detect the garlicky smell of dimethylselenide on the breath. Clinical signs that follow include respiratory distress, restlessness or lethargy, head down, droopy ears, anorexia, gaunt appearance, salivation, watery diarrhea, fever, sweating, tachycardia, teeth grinding, stilted gait, tetanic spasms and/or death. Clinical signs tend to progress quickly after they are first observed. Gross and histologic lesions include systemic congestion, pulmonary edema and petechial hemorrhages in and on the myocardium.

“Blind staggers” has historically been associated with subacute to chronic selenium. However, this association was due to its occurrence in known seleniferous areas. The areas with seleniferous soils also tend to have highly alkaline soils with high potential for excessive sulfur exposure. It has been stated that blind staggers cannot be reproduced with pure selenium compounds alone and likely involves other factors, such as alkaloid poisoning, starvation or polioencephalomalasia (O’Toole and Raisbeck, 1995). However, one can still find references that tie it to selenium (Underwood and Suttle, 1999; NRC, 2005).

Chronic selenosis, often referred to as “alkali disease,” is the result of long-term ingestion of seleniferous forages (NRC, 1983, 2005; Raisbeck, 2000). High selenium intake is generally for greater than 30 days and, due to plant selenium content, is usually associated with facultative accumulators, not indicator plants, although chronic selenosis can also be reproduced by long-term feeding of high inorganic selenium (Kaur *et al.*, 2003). Calves were chronically poisoned with selenite at 0.25mg/kg body weight daily for 16 weeks. In a similar study in yearlings, selenium as selenite at 0.8mg/kg/day and as selenomethionine at 0.28mg/kg/day resulted in alkali disease (O’Toole and Raisbeck, 1995). However, other studies did not produce alkali disease with selenium doses as high as 11.9mg/kg of diet in feeders or 118mg/kg body weight daily for 128 days in dairy cows (Ellis *et al.*, 1997; Lawler *et al.*, 2004). Differences in susceptibility to chronic selenium poisoning may be a product of historical exposure, variability in rumen microbial population and/or age-associated susceptibility. As stated previously, certain microbes can reduce selenium to non-bioavailable forms, resulting in decreased systemic absorption. Pigs develop chronic selenosis with exposure to selenium as low as 8mg/kg of diet (Goehring *et al.*, 1984; Mahan and Magee, 1991; Stowe and Herdt, 1992). And horses exposed to 20mg Se/kg DM for 3 weeks developed lesions (Stowe and Herdt, 1992).

Clinical signs of chronic selenosis include depression, weakness, emaciation, anemia, hair loss, anorexia, diarrhea, weight loss, lameness and death (Rosenfeld and Beath, 1964; O’Toole and Raisbeck, 1995; Underwood and Suttle, 1999; Raisbeck, 2000). Hoof wall abnormalities are frequently identified in cattle, horses and pigs, and include swelling of the coronary band, hoof deformities and/or separation and sloughing of the hoof wall. Hair loss from the base of the tail and switch in cattle, horses and mules is sometimes referred to as “bobtail disease.” Interestingly, sheep do not develop the alopecia or hoof lesions that are seen in cattle, but they have decreased wool growth rates. In pigs, goats and horses, there may be a general alopecia (Franke, 1934). Pigs also develop neurologic signs of paralysis (Goehring *et al.*, 1984).

Pathologic lesions of chronic selenium poisoning are generally related to hoof lesions and to the effects of starvation (Raisbeck, 2000). Lesions of nephritis, hepatic cirrhosis and myocardial necrosis can be expected. In pigs, bilateral malacia of the gray matter in the spinal cord can be seen.

Reproductive abnormalities are seen (Davis and Hall, 2011) in several species when excessive selenium is ingested. Field reports indicate that reproductive performance can be reduced without the other typical signs of alkali disease at 5–10ppm Se in diet (Olson *et al.*, 1970), but direct experimental evidence is lacking (Raisbeck, 2000). Decreased conception rate and an increased fetal resorption rate in cattle, sheep and horses were observed when they were fed natural diets containing 20–50mg Se/kg diet (Harr and Muth, 1972). Both rats exposed to 3ppm Se as seleniferous wheat (Munsell *et al.*, 1936) and mice exposed to 3ppm selenate in their drinking water (Schroeder and Mitchener, 1972b) had abnormally low rates of conception. Both deficiencies and excesses of selenium have been shown to adversely affect spermatogenesis, motility and viability in rodent models (Kaur and Bansal, 2005; Shalini and Bansal 2007, 2005; Boitani and Puglisi, 2008). If other species have similar effects, this could negatively affect herd reproductive performance. In addition, it must be noted that Se accumulates in the fetus at the expense of the dam (Puls, 1994). Thus, higher accumulation of selenium in the fetus may result in abortions, stillbirths or weak/lethargic calves. Yeager *et al.* (1998) reported a 7% abortion rate in a beef herd where cows had selenium concentrations suggestive of chronic selenosis and fetal hepatic selenium concentrations suggestive of toxicosis, but in a dosing study they only had one weak calf born that died shortly after birth. Although teratogenic effects of selenium poisoning are well documented in avian species, historical reports are all that are available for horses and sheep (Smith *et al.*, 1936; Beath *et al.*, 1939), although toxic plants in the environment may have also played roles. However, at least some of the adverse

effects on reproduction caused by excess selenium in ruminants are caused by interference with absorption and retention of copper that results in copper deficiency.

Selenosis in poultry has major effects in reproduction. Poor hatchability, embryonic deformities and embryonic death are common sequelae to selenium poisoning (Hoffman, 2002; Latshaw *et al.*, 2004; Hamilton, 2004).

## TREATMENT

The most effective treatment is to prevent excessive exposure. Although the maximal tolerable level for selenium was once set at 2 mg/kg of diet per day for all species, this has now been changed to 5 mg/kg of diet per day for ruminants (NRC, 2005). It is stated that this new tolerance for ruminants is appropriate for horses as well. Swines have a maximum tolerance level of 4 mg/kg of diet, for poultry it is set at 3 mg/kg of diet, and for fish it is set at 2 mg/kg of diet.

As there is no specific mechanism of chelation and removal of selenium in animals, the primary treatment protocol is of supportive care with both acute and chronic selenium poisoning. With chronic poisoning, it is important to understand the long-term commitment necessary to allow an animal with hoof lesions time to re-grow the hoof wall once exposure has been stopped. Especially with organic selenium's incorporation into body proteins, the time necessary to just decrease the body load of selenium, once excessive exposure has stopped, is quite long.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

Selenium deficiency and toxicity are problems that veterinarians, nutritionists and animal owners need to understand. The small difference between deficiency and toxicity in terms of dietary intake makes the risk of accidental selenium poisoning high. Many areas of the world have seleniferous soils which can cause poisoning via ingestion of natural forages grown on them. As there is no specific treatment for selenium toxicosis, it is critical that appropriate education be utilized in order to minimize the risks to the livestock industry.

Future research needs to address the mechanisms of physiologic damage caused by both acute and chronic selenium poisoning with differing chemical forms of selenium. With an understanding of the cellular mechanisms of selenium poisoning, more specific means of treatment might be developed. In addition, a clearer understanding of thresholds for chronic selenium poisoning is needed.

With the knowledge that certain ruminal microbes can reduce various forms of selenium to non-absorbable forms, preventive use of these microbes in seleniferous areas to prevent systemic accumulation and poisonings should be investigated.

## Sodium chloride (salt)

Larry J. Thompson

### INTRODUCTION

Sodium chloride is often referred to as table salt, common salt or just simply salt. Salt is an essential nutrient and can give an attractive taste to foods and feeds. It has been stated that salt is the only mineral compound for which animals can truly develop a craving.

Salt is a necessary nutrient for the health of animals and many nutrition texts divide it into separate requirements for sodium (Na) and chloride (Cl). Daily requirements for salt will increase due to lactation, exertion and increases in ambient temperatures. These same conditions will also require an increase in water intake, which must always be considered in any discussion concerning salt intake.

An excess of salt intake can lead to the condition known by various names including salt poisoning, hypernatremia, sodium ion toxicosis and water deprivation–sodium ion intoxication. The last name in this list is the most descriptive, giving both the result (sodium ion intoxication) and the most common predisposing condition (water deprivation).

### BACKGROUND

Sodium is the main cation and chloride is the main anion in the regulation of osmotic balance in the extracellular fluid (ECF) of the body. Serum sodium concentration and serum osmolality are normally maintained under precise control by homeostatic mechanisms involving thirst, antidiuretic hormone and renal reabsorption of filtered

sodium. Normal reference ranges for serum sodium in adult animals (given in mmol/l) include porcine 135–150, bovine 132–152, canine 141–152, feline 147–156 and equine 132–146 (Kaneko *et al.*, 1997). For sodium concentration measurement, mmol/l = mEq/l and can be used interchangeably. Hyponatremia is the result of the loss of excess sodium compared to loss of water and can be the result of a large number of disease processes and conditions. For a more complete explanation on the recognition and correction of hyponatremia the reader is directed to other references (Angelos and Van Metre, 1999).

Salt is normally present in animal diets at 0.5–1%. Production animals are often given free access to salt blocks or mineral mixes as supplements to the diet. Additional sources of salt may include high-saline ground water, brine or seawater. The use of whey as a feed or to produce wet mash can add dramatically to sodium intake. High concentrations of salt in the diet (up to 13%) have been used to limit feed intake of cattle. In general, animals can tolerate high concentrations of salt in the feed if they have free access to fresh water. Salt-deprived animals or animals not acclimated to high-salt feeds can overconsume these feeds making the animal prone to hypernatremia. Improperly formulated or improperly mixed feed can be an additional source of excess salt. Companion animal exposures to excess salt have included the use of salt as an emetic (this practice is no longer recommended) and the consumption of various salt-containing objects including rock salt and dough-salt mixtures. Hypernatremia has also been reported in animals treated with improperly mixed oral electrolyte solutions and remedies for diarrhea.

Excess ingested salt can be irritating to mucosal surfaces and can result in anorexia, vomiting or diarrhea.

Ingested dietary salt is approximately 90% absorbed across the gastrointestinal tract. Ingestion of excess sodium on an acute basis can result in hypernatremia with this condition being variously termed direct sodium ion toxicosis, acute sodium ion toxicosis or acute hypernatremia. Clinical signs develop within 1–2 days. The more common form of hypernatremia develops due to restricted water intake and is termed indirect sodium ion toxicosis, chronic sodium ion toxicosis or chronic hypernatremia. Clinical signs will develop over a period of 4–7 days but the early changes may be missed or ignored. There are several common reasons for restricted water intake including frozen water sources, unpalatable water sources, mechanical failure, overcrowding or naive animals and owner neglect.

## PHARMACOKINETICS AND MECHANISM OF ACTION

An increase in sodium intake leads to a rise in sodium concentration in the serum and a rapid distribution throughout the body. Osmolarity of the ECF is monitored by osmoreceptors in the hypothalamus and the body reacts to increases by stimulating thirst for increased water intake. Additionally, the release of antidiuretic hormone from the posterior pituitary will cause increased water retention by the kidneys. These responses should function to quickly restore normal osmolarity but may only be effective if the osmolar changes are gradual and sufficient water is available to the animal. As the sodium ion concentration of the serum increases, water will move out of the interstitium and intracellular fluid into the ECF along the osmotic gradient. Sodium will passively diffuse across the blood–brain barrier increasing the sodium concentration of the cerebral spinal fluid above the normal range (135–150 mmol/l). During this developing hypernatremia, the cells of the brain will also increase their intracellular osmolarity to prevent excess water loss to the ECF, which would cause cell shrinkage. If the hypernatremia develops too quickly and this protective mechanism fails, significant cell shrinkage occurs and the entire brain shrinks and pulls away from the calvarium resulting in the disruption of the blood supply to the brain. This can result in subarachnoid, subdural or intravascular hemorrhages (Hardy, 1989). In severe cellular dehydration, the result can be seizure-like activity and death. If the increase in sodium concentration of the brain cells continues, there will be an inhibition of glycolysis and a decrease in the energy available in the cell. While sodium will passively diffuse into the brain, it is an energy-requiring active process that transports sodium out. Thus the brain response to a rapid decrease in serum sodium is

delayed and the developing osmotic gradient will cause water to move into the brain causing swelling, cerebral edema and the development of clinical signs.

Changes in cellular osmolarity will occur in both acute and chronic hypernatremia situations, but changes to osmolarity on a chronic basis will involve the accumulation of more osmotically active organic compounds, termed idiogenic osmoles. These include taurine, myoinositol, glycerophosphoryl-choline, glutamate, glutamine, betaine and phosphocreatine. Maximum concentrations of idiogenic osmoles occur within 48–72 h and can account for 60% of the change in cellular osmolarity. Once the hypernatremia situation is corrected, the idiogenic osmoles will take 48–72 h to decrease back to normal levels. As in the acute situation, a rapid decrease in serum sodium will develop an osmotic gradient causing water to move into the brain with resulting cerebral edema and the development of clinical signs.

## TOXICITY

In all situations involving salt intake, the intake of water will have great impact and must also be considered. The acute toxic dose of sodium chloride is approximately 2.2 g/kg in swine, equine and bovine species with the ovine toxic dose approximately 6 g/kg (Osweiler *et al.*, 1985). Swine appear to be the most sensitive domestic animal and involve the greatest number of clinical reports. Both swine and poultry can be severely affected when water intake is severely restricted or with high-salt diets and only moderate water restriction. Increased water requirements will increase the susceptibility of lactating cows and sows to salt poisoning, making them more sensitive to sudden restrictions in water. The acute toxic dose of sodium chloride in dogs is given as 4 g/kg, but clinical signs have been reported for lesser ingestions (Barr *et al.*, 2004) and an ingestion greater than this was reported with only mild clinical signs. Horses appear to be rarely affected with classic salt poisoning but can develop it with conditions of increased salt intake and sudden water restriction. Horses are, however, subject to dehydration and electrolyte abnormalities especially under conditions of exercise and high ambient temperatures (Cohen *et al.*, 1993).

Clinical signs have best been described in swine and include loss of appetite, thirst, restlessness, pruritus and constipation. These early clinical signs can progress over several days to aimless wandering, head pressing, circling or pivoting around a limb. The animal may display seizure-like activity and assume a dog-sitting position, draw its head back in a jerking motion and fall over on its side (Osweiler *et al.*, 1985; Niles, 2004). Terminally, the

animal will be in lateral recumbency with paddling and opisthotonus. Cattle with acute excess salt intake may develop gastroenteritis, weakness, dehydration, tremors and ataxia. The cattle may appear to be blind and develop seizure-like activity or partial paralysis including knuckling over at the fetlocks. Terminally, cattle can also be in lateral recumbency with paddling and opisthotonus. Cattle can die within 24 h following the appearance of severe clinical signs. Recovered animals may drag the rear feet or knuckle over at the rear fetlock without exhibiting pain (Osweiler *et al.*, 1985). Poultry and other birds may exhibit clinical signs of depression, weakness, dyspnea and sudden death. Excess salt intake in the dog will result in vomiting within several hours of ingestion. The clinical signs can progress to diarrhea, muscle tremors and seizure-like activity. Increased severity of clinical signs in the dog have been seen when serum sodium levels have been above 180 mEq/l (Barr *et al.*, 2004).

Postmortem examination of salt-poisoned animals may include some degree of gastric irritation, including ulceration and hemorrhages. The content of the gastrointestinal tract may be abnormally dry. Histopathologic lesions may be limited to the brain and include cerebral edema and inflammation of the meninges. In swine, the appearance of eosinophilic perivascular cuffing is seen if the animal dies early in the syndrome with the lesion not found after 48 h. Brain sodium concentrations above 2000 ppm are considered diagnostic in cattle and swine. Upper normal brain sodium concentrations are 1600 ppm for cattle and 1800 ppm for swine, both on a wet weight basis. There is a paucity of data on normal brain sodium concentrations in other common domestic species but normal ranges should be similar. Serum sodium concentrations taken from the live animal will be significantly above the normal ranges listed previously. Postmortem analysis of aqueous humor, vitreous humor or cerebral spinal fluid will show a significant increase over values from normal animals (Osweiler *et al.*, 1995). Optimally, the values obtained should be compared to normal values for that species generated by the same laboratory.

## TREATMENT

Prior to the onset of clinical signs, the acute ingestion of salt can best be treated by allowing the animal full access to water and closely observing the animal for several hours. Emetics may be used in the dog if known ingestions occur and the animal is not yet showing clinical signs. However, most cases are discovered long after the excess salt ingestion or the water deprivation has occurred and the affected animals are showing obvious

clinical signs. The overriding concept of treatment is to slowly return the animal to normal water and electrolyte balance over a 2–3-day period of time. Quickly lowering the serum sodium concentration will increase the osmotic gradient between the serum and the brain with water following the gradient into the brain increasing the likelihood of severe cerebral edema. The prognosis for an animal hypernatremic from salt ingestion/water deprivation with significant clinical signs on either an acute or chronic basis should be guarded at best.

On a herd basis with large animals, water intake should be limited to 0.5% of body weight at hourly intervals until normal hydration is accomplished. Monitoring serum sodium concentration is the first step in treatment on an individual animal basis. This information can be used to correct the free water deficit (FWD) in the animal, based on the following formula:

$$FWD(1) = 0.6 \times \text{body weight (kg)} \\ \times [(\text{measured serum Na}/\text{normal serum Na}) - 1]$$

Not more than 50% of the FWD should be replaced in the first 24 h with the remaining deficit replaced in the following 24–48 h. Serum sodium levels should be lowered at a rate of 0.5–1.0 mEq/l/h, with the slower rate recommended for cases of chronic hypernatremia (Schaer, 2000). In acute hypernatremia without clinical dehydration, the use of 5% dextrose solution in combination with a loop diuretic has been suggested at 3.7 ml/kg/h to decrease serum sodium at 1 mEq/l/h (Barr *et al.*, 2004). Diuretics such as furosemide can be used to prevent the development of pulmonary edema during fluid therapy. The use of slightly hypertonic intravenous fluids has been recommended to reduce the likelihood of cerebral edema developing. Intravenous fluids should be made to approximate the serum sodium concentration of the animal, or the clinician may start with a solution containing 170 mEq/l of sodium and decrease this concentration as clinical signs improve (Angelos and Van Metre, 1999; Niles, 2004). If brain edema is suspected, the use of mannitol, dexamethasone or dimethyl sulfoxide may aid in control.

## CONCLUDING REMARKS

While the term “salt poisoning” may not be the most accurate way to describe the above syndrome, it is certainly in common usage. A similar and confusing term is “water intoxication” which has been used to describe the situation of excess water intake or infusion over a short period of time which can dramatically decrease the serum sodium concentration and make the serum hypoosmolar. Water intoxication has been used to

describe the exacerbation of cerebral edema when the correction of hypernatremia occurs too quickly. Water intoxication has also been used to describe the brain swelling and seizure-like activity which occurs when a normal animal drinks excessive amounts of water over a short period of time. In addition to the possible neurological effects, hemolysis has also been described (Middleton *et al.*, 1997). In the above situations, acute and dramatic osmotic changes are the cause.

# Sulfur

Jeffery O. Hall

## INTRODUCTION

Sulfur is a necessary dietary component that can be toxic at excessive concentrations. Animal bodies are about 0.15% sulfur by weight (NRC, 1989, 2006). Sulfur is incorporated into many essential molecules, including biotin, chondroitin sulfate, cartilage mucopolysaccharides, co-enzyme A, fibrinogen, glutathione, heparin, lipoic acid, mucins and thiamine (NRC, 1989, 1998, 2006). In addition to these biologically active compounds, sulfur is an intricate component of sulfur-containing amino acids, such as methionine, cysteine, cystine, homocysteine and taurine. With the exception of thiamine and biotin, all sulfur-containing compounds in the body can be synthesized from methionine (NRC, 1996). Thus, thiamine, biotin and methionine are essential nutrients in the diet of monogastric animals, but ruminant microbes can synthesize these compounds from inorganic sulfate in the diet (Block *et al.*, 1951). Species differences are such that cats cannot synthesize taurine from methionine, making it an essential nutrient in their diets. Recommended daily dietary intakes of sulfur are 0.15%, 0.14–0.26%, 0.15–0.2% and 0.2–0.25% of the diet for horses, sheep, beef cattle and dairy cattle, respectively (NRC, 1985, 1988, 1989, 1996).

Ruminants tend to be more sensitive to the toxic effects of dietary sulfur/sulfate due to efficient microbial conversion to bioactive sulfur species in the rumen. But both dietary and water sources of sulfur/sulfate have similar toxic potential and must be factored into the total daily intake in order to establish potential risk. Dietary feed sources that can contain high sulfur concentrations, which are frequently overlooked, include distiller's byproducts, wet and dry distiller's grains and gluten feeds. And these

products can have significant batch to batch variability in sulfur content, even from the same production plant. Due to their relative inexpensive nature, compared to grains, these high sulfur materials are more and more frequently being added to ruminant diets.

In addition to dietary sulfur, other sulfur-containing compounds can be toxic. Sulfur dioxide gas from industrial waste gas, as well as hydrogen sulfide gas from manure pits, natural gas production and crude oil production, can be toxic to livestock. The toxic effects of these gaseous forms of sulfur are better summarized separately from the dietary toxicoses.

Plants can accumulate high sulfur concentrations. High sulfate water can cause a dual increase in total daily sulfur intake by way of the water and ingested proximal vegetation. Plant sulfur concentrations have been shown to increase with increasing sulfate in the soil (Reddy *et al.*, 1981; Hardt *et al.*, 1991; Leustek and Saito, 1999). In soil matrixes, sulfate can be actively reduced and precipitated; however, this only sequesters the sulfur until environmental change allows the re-oxidation of the sulfur back to sulfate. During drought conditions, precipitated sulfur in the subsurface soil is exposed to greater oxygen and potentially re-oxidized. The resultant sulfate is then bioavailable for plant uptake during subsequent periods of normal or high precipitation.

## BACKGROUND

Sulfur is a non-metal within group VIA of the periodic table. This group is sometimes referred to as the

chalcogenides or ore-formers, since many metal ores are sulfide or sulfate salts. Sulfur has an atomic number of 16, an atomic weight of 32.07 and has four different naturally occurring atomic masses from 32 to 36 (Rosman and Taylor, 1998). It can occur in four different oxidation states:  $-2$  (sulfide),  $0$  (elemental sulfur),  $+4$  (sulfite) and  $+6$  (sulfate). All valence states, except elemental sulfur, are found in biologic molecules. Sulfur is utilized in the production of sulfuric acid, fertilizers, pigments, dyes, drugs, explosives, rubber, insecticides and detergents, as well as many inorganic salts and esters. Although uniformly found in nature, industrialized countries are the largest users of sulfur materials.

## PHARMACOKINETICS/ TOXICOKINETICS

When evaluating the absorption of sulfur, the chemical form must be considered. The intestinal mucosal absorption of sulfate is via an active carrier-mediated process that is also utilized by molybdate (Mason and Cardin, 1977). Active intestinal absorption of sulfate has been shown in sheep, rats, dogs, rabbits and hamsters (Bird and Moir, 1971). Similarly, the sulfur-containing amino acids and other sulfur-containing compounds are absorbed via specific transporter mechanisms across the intestinal mucosa (NRC, 2006). These specific transport processes are specific for the individual compounds. Rumen microbes convert a percentage of dietary sulfur-containing compounds to sulfide, which can then be incorporated into microbial sulfur-containing amino acids, thiamine, biotin, other microbial sulfur metabolites, or absorbed as sulfide. In addition to gastrointestinal absorption of sulfides, hydrogen sulfide can be absorbed across respiratory epithelium. Large amounts of sulfide, as hydrogen sulfide, produced in the rumen can be eructated, inhaled and absorbed (Dougherty *et al.*, 1965). And inhaled sulfide is important in sulfur toxicosis, as sheep that had their trachea blocked to prevent eructation and inhalation of sulfide did not succumb while those without tracheal block were poisoned (NRC, 2006).

Sulfur is widely distributed in the body. All tissues in the body have significant sulfur components, with the body being made up of approximately 0.15% sulfur (NRC, 2006). Absorbed sulfides and thiomolybdates, the primary toxic sulfur metabolites, are well distributed in the body. This is evidenced by the fact that thiomolybdate can deplete tissue stores of copper and sulfides can cross the blood-brain barrier (BBB) causing neurological effects.

Sulfur-containing amino acids and sulfate are extensively metabolized in order to produce biologically utilized sulfur compounds. In comparison, absorbed sulfide is efficiently metabolized in the liver to sulfate, with a

high first pass clearance (NRC, 2006). Inhaled sulfide would not be subject to the rapid hepatic removal that occurs for that absorbed from the gastrointestinal tract, resulting in increased circulating concentration that can result in neurologic effects.

Sulfur-containing compounds are eliminated by both renal and biliary routes. Just as molybdate can compete for the intestinal absorption sites for sulfate, it can also compete for reabsorption sites in the renal tubules (Friberg and Lener, 1986). The relative quantities of sulfur elimination from renal and biliary routes can differ depending on the form ingested. In sheep, Bird (1972) found the greatest percent elimination of sulfate was via urine, while that from taurine was predominantly eliminated in the bile. Intestinally absorbed sulfide efficiently undergoes hepatic metabolism to sulfate, which is eliminated in the urine (NRC, 2006).

## MECHANISM OF ACTION

Acute oral poisoning with elemental sulfur results in formation of hydrogen sulfide, as well as many other potential metabolites. The gastric and respiratory effects are postulated to be due to the coagulative effects of rumen-produced sulfurous acids and the irritating effects of hydrogen sulfide, respectively (Julian and Harrison, 1975; Kandyliis, 1984; Gunn *et al.*, 1987). However, the exact mechanisms are not well delineated. Inhaled ruminal sulfide at high concentrations may act in a similar mechanism to high concentrations of exogenous hydrogen sulfide gas, causing acute respiratory paralysis.

The mechanism of subacute sulfur poisoning is much better researched. This condition is correlated with the reduction of the sulfate or other forms of sulfur to sulfide in the rumen (Gould *et al.*, 1991, 1997; Loneragan *et al.*, 1998). The current literature suggests that inhibition of cytochrome C oxidase, which is essential for cellular respiration, is the primary mechanism (Smith *et al.*, 1977; Beauchamp *et al.*, 1984). But cerebral vasospasms and regional ischemia could also account for the localization of the lesions (Siesjo, 1984; McAllister, 1991). Although once thought to be associated with a true thiamine deficiency from either inhibition of rumen microbial production or cleavage of thiamine (Edwin and Jackman, 1982), it has been shown that systemic thiamine concentrations are within the normal range for most animals (Olkowski *et al.*, 1992; Gould, 2000). Slight decline in the blood thiamine concentration can also be seen in some animals (Olkowski *et al.*, 1991). However, thiamine supplementation in the presence of high sulfate/sulfur-associated polioencephalomalacia (PEM) alleviates the clinical disease (Olkowski *et al.*, 1992). This would indicate that the

sulfide or some other sulfur metabolite is either competitively inhibiting the cellular uptake/utilization of thiamine or therapeutic doses of thiamine diminish the effects of sulfide on the cytochrome C oxidase enzyme.

The subacute to chronic, indirect effects of excessive sulfur are seen in ruminants, due to the efficient conversion of sulfur compounds to sulfide. The sulfide can form insoluble salts with copper and zinc (Suttle, 1974), but it can also react with molybdenum and form thiomolybdate complexes which efficiently bind copper making it non-bioavailable (Suttle, 1991). Systemic copper decreases, associated with increased sulfur/sulfate, have been reported in sheep (Moshtaghi-Nia *et al.*, 1989; Van Niekerk and Van Niekerk, 1989a, b) and cattle (Wittenberg and Boila, 1988). High forage and water sulfur have also been associated with selenium deficiency (Ivancic and Weiss, 2001). Decreased serum and wool selenium has been reported with increasing dietary sulfate (White and Somers, 1977; White, 1980). In addition, increased soil sulfate inhibits plant uptake of selenium, thereby increasing the potential for inducing a selenium deficiency in ingesting herbivores (Newman and Schreiber, 1985), which may be an important mechanism in grazing animals.

## TOXICITY

Toxicity of sulfur can be divided into three main categories that are likely to be encountered. The first is acute oral poisoning. The second is subacute to chronic direct toxicosis. And the third is subacute to chronic indirect toxicosis, as a secondary interference with other essential minerals that result in deficiencies.

Reports of acute oral sulfur poisoning are scarce in the literature. In a group of Holstein heifers, sulfur ingested at 0.85–3.8 g/kg body weight resulted in high morbidity and moderate mortality (Gunn *et al.*, 1987), while 20 heifers given 250 g sulfur in grain had high mortality (Julian and Harrison, 1975). Ewes fed a barley–sulfur mix that provided approximately 40–45 g sulfur/ewe were poisoned (White, 1964). Five horses administered 300 g sulfur succumbed to sulfur poisoning (Ales, 1907).

Clinical and pathologic manifestations of acute oral sulfur poisoning are similar across species (White, 1964; Julian and Harrison, 1975; Gunn *et al.*, 1987). Abdominal pain, colic, rumen stasis, fetid diarrhea, dehydration, metabolic acidosis, tachypnea, recumbency and hydrogen sulfide smell are expected clinical signs. Irritation, edema and hemorrhage of the gastrointestinal tract and respiratory tract also should be expected. In addition, renal tubular necrosis can be seen.

Monogastric animals are much less susceptible to the subacute direct and indirect toxic effects of excessive

sulfur intake than ruminants. Pigs can tolerate 1000 mg/l sulfur in the drinking water with only a mild cathartic effect (Paterson *et al.*, 1979) and 0.42% in the diet for several months without adverse effects (Dale *et al.*, 1973). Similarly, chicks had decreased growth rates at 1.2% dietary sulfur (Leach *et al.*, 1960). And chickens had decreased egg production, decreased feed intake and deaths at 4000 mg/l sulfate in their drinking water (Adams *et al.*, 1975). Since the indirect toxic effects of excessive sulfur are related to rumen conversion to sulfide, these effects are not observed in monogastric animals.

In contrast, for sheep, beef cattle and dairy cattle the maximum tolerable content of sulfur in the total diet is 0.4% (NRC, 1985, 1988, 1996), while concentrations slightly below this tolerable content can occasionally result in toxic effects (Gould *et al.*, 1991). Since dietary toxicity is not mutually exclusive, as sulfur and sulfate ion can have the same clinical effects, total doses of sulfur/sulfate from both water and dietary material must be taken into account when evaluating potential toxicity (Suttle, 1974). For example, water sulfate content of 500 mg/l would provide approximately half of the recommended maximal daily intake for ruminants. In ruminants, the typical clinical presentation of sulfur poisoning is one of ataxia, weakness, blindness, recumbency, seizures and death.

Subacute ingestion of toxic doses of sulfate/sulfur has been associated with PEM, a necrotizing lesion of the brain (Beke and Hironaka, 1991; Gould *et al.*, 1991; Olkowski *et al.*, 1992; Hamlen *et al.*, 1993; McAllister *et al.*, 1997). Gross and histologic lesions are primarily in the brain, but ruminal changes can be observed. Gross pathologic lesions include a darkening of the rumen contents from precipitated sulfide salts, swelling of the cerebral hemispheres, softening of the cerebral hemispheres and yellow discoloration of the cortical gray matter. Histological lesions include necrosis of the cortical gray matter and occasional areas of necrosis in the thalamus or midbrain. The clinical condition can be an additive effect of the total sulfur in the diet and sulfate in the drinking water (Beke and Hironaka, 1991). PEM has been reported to be associated with high sulfur/sulfate ingestion in cattle (Beke and Hironaka, 1991; Gould *et al.*, 1991; Hamlen *et al.*, 1993), pigs (Dow *et al.*, 1963) and sheep (Olkowski *et al.*, 1992). However, sodium ion poisoning in pigs was likely the primary causative factor, as the exposure was to sodium sulfate.

The peak rumen production of hydrogen sulfide can be somewhat delayed from the time of initiating high sulfur intake. Peak rumen gas cap sulfide occurred at 1–3 weeks after placing cattle on a high sulfur diet (Gould *et al.*, 1997). But, continuing exposure resulted in a gradual decline in the gas cap sulfide content. This would indicate an adaptation of the rumen microbes to favor direct utilization of the sulfide or diminished rates of production.

Subacute to chronic sulfur-induced mineral deficiencies can result in severe health problems. Copper

deficiency can cause poor growth, weakness, poor immune function, poor reproductive function and death. In addition, sulfur-induced copper deficiency may play a role in PEM (Gooneratne *et al.*, 1989). Severe copper deficiency also causes myelin degeneration (enzootic ataxia) in lambs, deer and other ruminants (Cordy, 1971; Faye *et al.*, 1991; Audige *et al.*, 1995). Sulfate-induced selenium deficiency can cause poor growth, weakness, poor immune function, poor reproductive function, damage to the cardiac or skeletal muscles and death.

## TREATMENT

Treatment for acute sulfur poisoning is predominantly supportive in nature, with removal of the causative material, as well as administration of fluids and electrolytes. However, the human literature points to successful treatment of acute hydrogen sulfide poisoning by induction of methemoglobinemia with nitrite to allow for the formation of sulfmethemoglobin, similar to therapeutic protocols for treatment for cyanide poisoning (Stine *et al.*, 1976; Peters, 1981). This type of therapy may also be beneficial in the treatment of subacute direct sulfur poisoning. Since sulfides act on and split disulfide bridges, the use of oxidized glutathione or other simple disulfide compounds could be protective or antidotal (Smith and Abbanat, 1966). The use of thiamine in the treatment of PEM has been suggested to be beneficial, even though there is no overt thiamine deficiency. The primary treatment of indirect mineral deficiencies resultant from high sulfur intake would also include enhanced supplementation of copper and potentially selenium. In some cases in which limitation of water or forage sulfur intake is not possible, use of chelated copper and selenium becomes important in order to bypass the binding of copper in the rumen and competitive inhibition of selenate from the intestinal tract.

In addition to direct treatment, management can play a role in the prevention of sulfur poisoning. Testing of water and dietary materials will identify high sulfur prior to utilization. With this information, management strategies can be utilized that would incorporate the sulfur at gradually increasing content in an attempt to allow for microbial adaptation.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

Although much is known about the different clinical disease conditions that excessive sulfur can cause, treatment remains only somewhat effective. Thus, it is important

to evaluate the use of nitrite- or disulfide-containing compounds in the treatment of domestic animals.

## Zinc

Tam Garland

## INTRODUCTION

Zinc (Zn) is a transitional metal in group XII on the periodic chart and is the fourth most commonly used metal today. It is a moderately reactive metal with a common valence state of +2. It is also an essential element in mammals and birds and is a component of approximately 200 metalloenzymes. Although zinc has an essential role in nutrition and consequences of nutritional deficiency, this chapter will focus on its toxicity.

## BACKGROUND

As the fourth most commonly used metal it is expected to be found in a variety of places with a multitude of uses. Zinc is an economical metal to use and is relatively non-toxic. Table 44.1 details some of those uses. Since zinc has nutritional qualities, it is not uncommon to find it added as a supplement to feed. Problems with toxicity generally occur when the levels are 1000 parts per million (ppm) or greater.

PHARMACOKINETICS/  
TOXICOKINETICS

Ingested zinc is primarily absorbed from the duodenum and the intestine by a carrier-mediated mechanism. Approximately 25 to 50% of ingested zinc is absorbed.

TABLE 44.1 Uses and purposes of zinc

Zinc is used in:	Its purpose is:
Galvanized steel	Prevents corrosion
Parkerize steel	Prevents rust and corrosion
Used in numerous metal alloys	Brass, nickelled silver, typewriter metal, various soldering formulas, German silver
Primary metal	American pennies, nuts and bolts
Die casting	Automotive industry
Zinc oxide	Paints, sun protectants, rubber activator, diaper rash ointments
Wall tiles	Germicidal properties
Zinc chloride	Wood preservative and deodorant
Zinc methyl ( $\text{Zn}(\text{CH}_3)_2$ )	Number of organic syntheses
Zinc stearate	A lubricative plastic additive

However, absorption of zinc is influenced by many factors, including whether or not food is in the stomach. Plant phytates can bind zinc and in an alkaline pH environment can form insoluble complexes. Similarly zinc absorption is decreased in the presence of phosphates and calcium in the diet. However, the presence of some peptides, amino acids and ethylenediamine tetra acetic acid disodium (EDTA) may cause an increase in absorption. Generally, the stomach acid provides for rapid release of zinc from ingested metallic objects.

Once zinc has been absorbed it is bound to plasma albumin and to macroglobulins, and transported to the liver. Zinc is extracted by the liver and returned to the bloodstream for distribution to the liver, pancreas, kidney and spleen which all rapidly accumulate the zinc. These tissues, as well as muscle and prostate, are induced to synthesize metallothionein in the cells.

Under normal dietary conditions, excess zinc is excreted through the feces. Nevertheless, excretion of zinc, especially in toxic situations, is limited. Excretion occurs through the bile and feces but may also occur through urine (Abdel-Mageed and Oehme, 1990) and saliva.

## MECHANISM OF ACTION

The mechanism of action producing clinical signs is not well defined or understood. The characteristic clinical signs are more easily recognized. The most recognized abnormality observed is severe intravascular hemolysis and gastroenteritis. This may be a result of excess zinc interfering with copper and iron storage and utilization, resulting in a suppression of hematopoiesis.

Diets high in zinc interfere with hepatic copper storage and may compete with calcium for intestinal absorption.

## TOXICITY

The different forms of zinc have different toxicities. The zinc salts have a median lethal dose (LD<sub>50</sub>) of approximately 100 mg/kg body weight. Zinc oxides are less toxic. Zinc oxides are frequently found in ointments, such as for preventing sunburn or treating diaper rash. Dogs often ingest it when it is applied topically to them or to someone they can lick it off. Dogs also ingest the ointment by chewing on the tube container. It has been estimated that the toxic dose is approximately 108 grams of zinc in the dog (Breitschwerdt *et al.*, 1986).

The ingestion of pennies, which are 96% zinc (Latimer *et al.*, 1989), by dogs has resulted in the development of a subacute zinc toxicosis. The pennies remain in the acidic environment of the stomach and slowly release metallic zinc. It is unclear how many pennies are required to produce a toxicosis. The pennies can be vomited or passed in the feces prior to presentation at the veterinary clinic.

Other forms of zinc-containing hardware such as transport kennel bolts or machine nuts and bolts have caused problems in animals. Analysis of these objects has shown them to be about 97% zinc (Breitschwerdt *et al.*, 1986; Torrance and Fulton, 1987). They remain in the stomach producing a subclinical toxicosis or are vomited or passed out prior to the animal's presentation.

Other sources of toxicity have been galvanized wire used in cages in aviaries (Reece *et al.*, 1986) and for housing ferrets (Straube *et al.*, 1980). The toys an animal selects may be made almost entirely of zinc (Bexfield *et al.*, 2007), and may not be a toy necessarily designed for animals.

An additional component of zinc toxicosis is acute renal failure observed in some dogs (Breitschwerdt *et al.*, 1986). The clinical findings include hypercreatinemia, azotemia, hyperphosphatemia and granular casts in the urine (Breitschwerdt *et al.*, 1986; Torrance and Fulton, 1987; Latimer *et al.*, 1989). Other signs of acute intoxication are pancreatitis and acute arthritis. Also, non-viable newborns may be observed with zinc intoxication.

Foals are susceptible to zinc intoxication. It appears to be a chronic zinc toxicosis. Initially, the foals have non-painful joint enlargement lasting 7–21 days. They are reluctant to rise and have stiff gait and increased joint fluid (Gunson *et al.*, 1982).

Other livestock have early signs of lethargy and anorexia followed by diarrhea. Later, they display a decreased rate of gain or decreased milk production. As the toxic condition progresses, the animals have anemia and icterus. Other signs include exophthalmia, polydipsia, polyphagia and seizures.

Generally most species display some degree of hemolytic anemia, often with an erythrocytic regenerative response. Additionally, there is renal damage with hematuria, urinary casts and proteinuria. Diagnostically, there may be a radiodense area in the gastrointestinal tract indicating the presence of zinc or some other metal such as lead. Postmortem lesions include renal tubular necrosis, hepatocyte necrosis and gastroenteritis.

## TREATMENT

As with many metal intoxications, removal of the source of the toxin from the animal, followed by supportive therapy, are critical to the patient's recovery. This procedure with zinc will result in dramatic drops in serum and tissue levels within a relatively short time. Removal of the source will allow the normal excretory pathways to work appropriately.

Particularly when treating foals it is important to evaluate the copper status of the animal. Copper and zinc seem to work in tandem and adding copper to copper-deficient animals may help decrease the overriding effects of zinc.

Supportive care is critically important as the gastroenteritis and anemia must be addressed. The vomiting, in species capable of vomiting, has usually resulted in severe gastroenteritis. Vomiting may be controlled with metoclopramide (0.2–0.4 mg/kg) administered every 6 hours intramuscularly, subcutaneously or *per os*. Blood transfusions may be in order to address the anemia. Additionally, fluid therapy with a balanced solution such as lactated Ringer's solution should be considered. Good supportive care includes continuous monitoring of

various blood parameters such as red blood cells, platelets, packed cell volume and serum chemistries including liver enzymes, serum urea nitrogen and electrolytes. Treatment efforts must be directed at correcting pancreatic, renal and/or liver dysfunctions that are so closely associated with zinc intoxication.

Chelation therapy is an option in the patient's care. Chelation therapy is effective but not without risk and so must be evaluated with regard to the patient's condition. Patient conditions requiring evaluation include the hydration status, the degree of dysfunction of the excretory organs and the severity of the serum zinc concentration. Another important factor is whether the offending object could be removed from the patient. The most commonly suggested chelator is calcium disodium EDTA. Calcium disodium EDTA is most commonly used to treat lead intoxication and the dose for zinc intoxication has thus been extrapolated (100mg/kg, divided into four doses per day administered subcutaneously, diluted in 5% dextrose in water to decrease local irritation). Especially with chelation therapy, daily monitoring of the patient is essential to determine the length of therapy.

## CONCLUSIONS

Evidence of pancreatitis and liver and kidney dysfunction must be considered along with gastroenteritis and a hemolytic event when considering the differentials. The clinical sign of acute gastroenteritis is common to viral and bacterial diseases, parasitic diseases and various neoplasms. Gastroenteritis and a hemolytic event must be differentiated from other metal intoxications such as

copper poisoning. Additional considerations include acetaminophen or onion intoxication, mustard poisoning, immune-mediated diseases and certain snake bites.

As zinc is a very economically useful metal it is likely to be found in more products that animals are exposed to in various fashions. It would be beneficial to have a larger array of safe chelation products. Unfortunately, the importance of chelation therapy outweighs the available markets for the product. Therefore it is unlikely research dollars will be directed at finding new chelation therapies.

# Organophosphates and carbamates

Ramesh C. Gupta and Dejan Milatovic

## INTRODUCTION

Organophosphates (OPs) and carbamates (CMs) are commonly used as pesticides in agriculture, industry and around the home/garden throughout the world. In addition, these chemicals are used as parasiticides in veterinary medicine. Both types of chemicals produce their toxicity by virtue of inhibition of acetylcholinesterase (AChE) enzyme, which terminates the action of the neurotransmitter acetylcholine (ACh) at the synapses in nervous tissue and at the neuromuscular junctions (NMJs). These chemicals are referred to as “anticholinesterases.” Some of the OPs with strong AChE inhibiting potential are also used as nerve agents or nerve gases in chemical warfare.

Since many compounds of both classes are extremely toxic and lack species selectivity, their inadvertent/accidental use continues to pose a threat to the environment, human and animal health, wildlife and aquatic systems. Small animals often encounter poisoning with these insecticides by malicious activity, while livestock by ingesting freshly sprayed crop or contaminated feed. Although these compounds are neurotoxicants, they produce a variety of cholinergic and non-cholinergic effects. The latest evidence suggests that while cholinergic mechanisms play a critical role in the initial stage of toxicity, neuronal damage/death appears to occur through non-cholinergic mechanisms. OPs and CMs are discussed here together because they produce similar toxic effects in poisoned animals. This chapter covers various aspects of toxicity of OP and CM compounds and therapeutic measures in animals. For more details, readers are referred to some recent

publications elsewhere (Gupta, 2006, 2009; Satoh and Gupta, 2010; Gupta and Milatovic, 2011).

## BACKGROUND

The first OP compound, tetraethyl pyrophosphate, was synthesized in 1854 by Philipe de Clermont. In 1932, Lange and Kruger described the synthesis of dimethyl and diethyl phosphorofluoridate. Based on the chemistry of these compounds, Gerhard Schrader (a chemist at the I.G. Farbenindustrie) led the exploration of OP class of compounds that could be used as insecticides. One of the earliest OP insecticides synthesized by Schrader was parathion, which is still used worldwide. Prior to World War II (WWII), the German Ministry of Defense developed highly toxic OP compounds of G series (tabun, sarin and soman) and diisopropyl phosphorofluoridate. In the 1950s, OP compounds with super toxicity of V series, such as VX and VR, were synthesized in the UK and the Soviet Union. After WWII, thousands of OPs have been synthesized in the search for compounds with species selectivity, i.e., more toxicity to insects and less toxicity to mammals. Malathion is an example. This compound has been used for more than half a century as the most popular insecticide. Today, more than 200 OPs are in use for a variety of purposes, such as protection of crops, grains, gardens, homes and public health.

The first carbamate compound, physostigmine (eserine alkaloid), was isolated from calabar beans (ordeal poison) of a perennial plant *Physostigma venenosum* in the

**FIGURE 45.1** General structure for organophosphorus (I) and carbamate (II) insecticides. (Adapted from [Timchalk, 2006](#).)

mid-1860s. The compound was used to treat glaucoma. About 50 years later, an aromatic ester of carbamic acid, neostigmine, was synthesized and used in the treatment of myasthenia gravis. Most of the carbamates (esters of carbamic acid) that are used as pesticides were synthesized in the 1960s and 1970s. Carbaryl was the first CM compound

used as an insecticide. The most toxic compound of this class, aldicarb, was synthesized by mimicking the structure of ACh. Like OPs, thousands of CMs have been synthesized, but less than two dozen compounds have been used practically. Today, CMs are preferred for pesticide use over OPs because some OPs have been found to be extremely toxic, while others cause delayed neuropathy in animals as well as in humans. In essence, both OPs and CMs have broad applications in agriculture and veterinary medicine and as a result of their indiscriminate use acute poisonings often result in animals, birds, fish and wildlife.

Basic structures of organophosphorus and carbamate compounds are shown in [Figure 45.1](#). There are at least 13 types of OPs (see [Table 45.1](#)). Despite differences in chemical structures, all OPs share one thing in common: they all have a pentavalent phosphorus atom and a characteristic phosphoryl bond ( $P=O$ ) or thiophosphoryl bond ( $P=S$ ). Essentially, OPs are esters of phosphoric acid with varying combinations of oxygen, carbon, sulfur and/or nitrogen attached. Of course, the chemistry of these compounds

Note: Adapted from Marrs (1993).

is much more complex. The OPs that are derivatives of phosphoric or phosphonic acid possess anticholinesterase activity, unlike those that are derivatives of phosphinic acid. Usually, OP compounds have two alkyl substituents and an additional substituents group (leaving group, which is more labile to hydrolysis than the alkyl group). Basically, some OPs (such as dichlorvos, monocrotophos and trichlorfon) are direct AChE inhibitors, while those of

phosphorothioates type (such as bromophos, diazinon, fenitrothion and parathion) possess minimal or no anticholinesterase (anti-AChE) activity and require desulfuration to the analogous oxon before acquiring anti-AChE activity and hypercholinergic effects. Also, OPs which are used as defoliant (S,S,S-tributyl phosphorotrithioate and S,S,S-tributyl phosphorotrithioite) and herbicides (glyphosate and gluphosinate) are of very low mammalian toxicity.

TABLE 45.2 A brief chemical description of commonly used OP pesticides

Chemical	Chemical name	Mol. wt.	Oral LD <sub>50</sub> in rat (mg/kg)	Dermal LD <sub>50</sub> in rabbit (mg/kg)
Acephate	<i>O,S</i> -dimethyl acetylamiidothiophosphate	183.17	866	>2000
Azinphos-ethyl	<i>O,O</i> -diethyl <i>S</i> -[(4-oxo-1,2,3-benzotriazin-3(4 <i>H</i> )-yl)methyl] dithiophosphate	345.38	13	250
Azinphos-methyl	<i>O,O</i> -dimethyl <i>S</i> -[(4-oxo-1,2,3-benzotriazin-3(4 <i>H</i> )-yl)methyl] dithiophosphate	317.32	5	220
Bromophos	<i>O</i> -(4-bromo-2,5-dichlorophenyl) <i>O,O</i> -dimethyl thiophosphate	366.00	1600	2188
Cadusaphos	<i>S,S</i> -di- <i>sec</i> -butyl <i>O</i> -ethyl dithiophosphate	270.40	391	143
Carbophenothion	<i>S</i> -[(4-chlorophenyl)thio] methyl] <i>O,O</i> -diethyl dithiophosphate	342.87	6	22
Chlorethoxyphos	<i>O,O</i> -diethyl <i>O</i> -(1,2,2,2-tetrachloroethyl) thiophosphate	336.00	1.8	12.5
Chlorfenvinphos	2-chloro-1-(2,4-dichloro-phenyl)vinyl diethyl phosphate	359.57	12	3200
Chlorpyrifos	<i>O,O</i> -diethyl <i>O</i> -(3,5,6-trichloropyridin-2-yl) thiophosphate	350.59	135	2000
Chlorpyrifos-methyl	<i>O,O</i> -dimethyl <i>O</i> -(3,5,6-trichloropyridin-2-yl) thiophosphate	322.53	941	2000
Coumaphos	<i>O</i> -(3-chloro-4-methyl-2-oxo-2 <i>H</i> -chromen-7-yl) <i>O,O</i> -diethyl thiophosphate	362.77	13	–
Crotoxyphos	1-phenylethyl (2 <i>E</i> )-3-[(dimethoxyphos-phoryl)oxy]but-2-enoate	314.27	125	385
Cyanophos	<i>O</i> -(4-cyanophenyl) <i>O,O</i> -dimethyl thiophosphate	243.22	610	800
Demeton-O	<i>O,O</i> -diethyl <i>O</i> -[2-(ethylthio)ethyl] thiophosphate	258.34	2.5	8
Diazinon	<i>O,O</i> -diethyl <i>O</i> -(2-isopropyl-6-methylpyrimidin-4-yl) thiophosphate	304.35	300	379
Dichlorvos	2,2-dichlorovinyl dimethyl phosphate	220.98	25	59
Dicrotophos	(1 <i>E</i> )-3-(dimethylamino)-1-methyl-3-oxoprop-1-en-1-yl dimethyl phosphate	237.19	22	223
Dimethoate	<i>O,O</i> -dimethyl <i>S</i> -[2-(methylamino)-2-oxoethyl] dithiophosphate	229.26	250	400
Disulfoton	<i>O,O</i> -diethyl <i>S</i> -[2-(ethylthio)ethyl] dithiophosphate	274.40	2	6
Ethion	<i>O,O,O',O'</i> -tetraethyl <i>S,S'</i> -methylene bis(dithiophosph-ate)	384.48	27	915
Famphur	<i>O</i> -[4-[(dimethylamino)sulfonyl]phenyl] <i>O,O</i> -dimethyl thiophosphate	325.34	35	2730
Fenamiphos	ethyl 3-methyl-4-(methylthio)phenyl isopropylamidophosphate	303.36	15.3	–
Fenitrothion	<i>O,O</i> -dimethyl <i>O</i> -(3-methyl-4-nitrophenyl) thiophosphate	277.23	250	1300
Fenthion	<i>O,O</i> -dimethyl <i>O</i> -[3-methyl-4-(methylthio)phenyl] thiophosphate	278.33	255	330
Fonofos	<i>O</i> -ethyl <i>S</i> -phenyl ethylphosphonodi-thioate	246.33	8	25
Glyphosate	<i>N</i> -(phosphonomethyl)-glycine	169.07	4300	>5000
Gluphosinate ammonium	2-amino-4-[hydroxy(methyl)phosphoryl]butanoic acid ammoniate	198.16	2000	>4000
Glyphosine	<i>N,N</i> -bis(phosphonomethyl)glycine	263.08	3925	>5010
Isazophos	<i>O</i> -(5-chloro-1-isopropyl-1 <i>H</i> -1,2,4-triazol-3-yl) <i>O,O</i> -diethyl thiophosphate	313.75	40	>3100
Isufenphos	isopropyl 2-[[ethoxy(isopropylamino)phosphorothioyl]oxy]benzoate	345.40	32	162
Malathion	diethyl 2-[(dimethoxyphos-phorothioyl)thio] succinate	330.36	885	4000
Methamidophos	<i>O,S</i> -dimethyl amidothiophosphate	141.13	13	110
Methodathion	<i>S</i> -[(5-methoxy-2-oxo-1,3,4-thiadiazol-3(2 <i>H</i> )-yl)methyl] <i>O,O</i> -dimethyl dithiophosphate	302.33	25	200
Methyl parathion	<i>O,O</i> -dimethyl <i>O</i> -(4-nitrophenyl) thiophosphate	263.21	9	63
Mevinphos	methyl (2 <i>E</i> )-3-[(dimethoxyphos-phoryl)oxy]but-2-enoate	224.15	3	16
Monocrotophos	dimethyl (1 <i>E</i> )-1-methyl-3-(methylamino)-3-oxoprop-1-en-1-yl phosphate	223.16	8	354
Omethoate	<i>O,O</i> -dimethyl <i>S</i> -[2-(methylamino)-2-oxoethyl] thiophosphate	213.19	50	1400
Paraoxon	diethyl 4-nitrophenyl phosphate	275.19	1.8	–
Parathion	<i>O,O</i> -diethyl <i>O</i> -(4-nitrophenyl) thiophosphate	291.26	3	6.8
Phenthoate	ethyl [(dimeth-oxyphosphoro-thioyl)thio] (phenyl)acetate	320.36	200	4000
Phorate	<i>O,O</i> -diethyl <i>S</i> -[(ethylthio)methyl] dithiophosphate	260.38	1.6	2.5
Phosmet	<i>S</i> -[(1,3-dioxo-1,3-dihydro-2 <i>H</i> -iso-indol-2-yl)methyl] <i>O,O</i> -dimethyl dithiophosphate	317.32	147	3160
Phosphamidon	(1 <i>Z</i> )-2-chloro-3-(diethylamino)-1-methyl-3-oxoprop-1-en-1-yl dimethyl phosphate	299.69	15	125
Phoxim	phenylglyoxalo-nitrile oxime, <i>O,O</i> -diethyl phosphorthioate	289.30	1845	1126
Profenofos	<i>O</i> -(4-bromo-2-chlorophenyl) <i>O</i> -ethyl <i>S</i> -propyl thiophosphate	373.63	400	472
Propetamphos	isopropyl (2 <i>E</i> )-3-[(ethylamino)(methoxy)phosphorothioyl]oxy} but-2-enoate	281.31	82	2300
Quinalphos	<i>O,O</i> -diethyl <i>O</i> -quinoxalin-2-yl thiophosphate	298.30	65	340
Ronnel	<i>O,O</i> -dimethyl <i>O</i> -(2,4,5-trichlorophenyl) thiophosphate	321.55	1250	2000
Sulfotepp	<i>O,O,O,O</i> -tetraethyl dithiodiphosphate	322.32	5	–
Sulprofos	<i>O</i> -ethyl <i>O</i> -[4-(methylthio)phenyl] <i>S</i> -propyl dithiophosphate	322.45	107	820
Terbufos	<i>S</i> -[( <i>tert</i> -butylthio)methyl] <i>O,O</i> -diethyl dithiophosphate	288.43	1.6	1
Triazophos	<i>O,O</i> -diethyl <i>O</i> -(1-phenyl-1 <i>H</i> -1,2,4-triazol-3-yl) thiophosphate	313.32	83	280
Trichlorfon	dimethyl (2,2,2-trichloro-1-hydroxyethyl)phosphonate	257.44	630	>2100

## OP PESTICIDES

The majority of OP compounds are used as pesticides, and a brief chemical description for commonly used compounds is given in [Table 45.2](#).

Chemical structures of some of the commonly used OP pesticides are shown in [Figure 45.2](#).

## OP NERVE AGENTS/GASES

OP nerve agents include tabun (GA), sarin (GB), soman (GD), cyclosarin (GF), venom toxin (VX) and Russian VX (VR). These compounds are highly toxic and pose continuous threats for the lives of humans as well as animals, because they can be used as chemical weapons of mass destruction (WMD). So far these agents have been used by dictators and terrorists. In some incidents, animals have been victims of military operations. These compounds produce toxicity by directly inhibiting AChE, and are much more potent than OP pesticides, as they cause lethality to animals in the micrograms range. Their chemical structures are shown in [Figure 45.3](#). For details of toxicity of these compounds, refer to [Watson et al. \(2006, 2009\)](#) and [Radilov et al. \(2009\)](#).

## CARBAMATES

The carbamate (CM) compounds are esters of carbamic acid. Unlike OPs, CM compounds are not structurally complex. Chemical structures of some commonly used CM insecticides are shown in [Figure 45.4](#), and a brief toxicological data of CMs is provided in [Table 45.3](#). For the details of CMs, readers are referred to [Gupta \(2006\)](#) and [Gupta and Milatovic \(2011\)](#). Currently, the volume of CMs used exceeds OPs because they are relatively safer than OPs.

## PHARMACOKINETICS OF OPs AND CMs

Pharmacokinetics deals with the rate limiting processes of absorption, distribution, metabolism and excretion (ADME). The ADME of OP and CM insecticides in animals have been described ([Tomokuni et al., 1985](#); [Gupta, 1994](#); [Wu et al., 1996](#); [Timchalk, 2006, 2010](#); [Gupta et al., 2011](#)). These insecticides gain entry into the body mainly through oral, dermal or inhalation exposure. Ingestion encounters with contaminated feed/food with pesticides

residue, while dermal exposure is more relevant when these insecticides are used as ectoparasiticides in the form of dust, dip or oily solution. Inhalation of airborne insecticides occurs during or soon after aerial spray, particularly due to chemical drift. Once the insecticide reaches at a portal of entry, it is available for absorption. It is established that following absorption, these insecticides are well distributed in tissues throughout the body. Being lipophilic, maximum levels of these compounds are usually found in the adipose tissue and brain.

In terms of metabolism, OP insecticides may follow either activation or detoxification, or both. Activation implies that the metabolite is more toxic than the parent compound, e.g., the conversion of malathion to malaoxon. This process is often referred to as "lethal synthesis." On the other hand, detoxification implies that the metabolite is less toxic than the parent compound, e.g., the conversion of malathion to malathion monoacid and malathion diacid. Unlike OPs, CMs are metabolized to less toxic or nontoxic metabolites. However, some of the metabolites of carbamates are quite toxic. For example, the two major metabolites of carbofuran (3-hydroxycarbofuran and 3-ketocarbofuran) have a significant impact on overall toxicity of carbofuran ([Gupta, 1994](#)).

A bulk of the metabolic activation and detoxification of OPs and CMs occur within the liver ([Tang et al., 2005](#); [Sogorb and Vilanova, 2010](#); [Vacondio et al., 2010](#)). Due to extensive metabolism of these insecticides in the body, only few metabolites are excreted in the urine that can be used as biomarkers of insecticides exposure. Residues of some OPs and CMs can also be detected in the feces, saliva and milk. In the case of dead animals, residue of OPs and CMs is likely to be detected in the GI content (following ingestion), adipose tissue and brain.

## MECHANISM OF ACTION

OP and CM insecticides share a common mode of toxicological action associated with their ability to inhibit the AChE enzyme within the nervous tissue and at the neuromuscular junction (NMJs). Both types of insecticides have a high affinity for binding to and inhibiting AChE, an enzyme specifically responsible for the hydrolysis of the neurotransmitter ACh. Since the cholinergic system is widely distributed within both the central and peripheral nervous systems, chemicals that inhibit AChE are known to produce a broad range of well-characterized symptoms of anticholinesterases. A graphic representation for the comparison of the AChE inhibition dynamics for the interaction of ACh, carbaryl (CM) or chlorpyrifos-oxon (OP) with AChE is shown in [Figure 45.5](#) ([Timchalk, 2006](#)). The cholinesterases (ChE) are serine hydrolases that catalyze the breakdown of ACh through an

FIGURE 45.2 Chemical structures of commonly used OP pesticides.

FIGURE 45.3 Chemical structures of OP nerve agents.

acyl-transfer, where water is the acceptor molecule to which the substrate acyl moiety is transferred. A serine oxygen of the active site gorge in ChEs carries out a nucleophilic attack on the electrophilic carbon of the carbonyl group of ACh, resulting in an acetylated enzyme intermediate and the release of choline. Deacetylation occurs when an attacking water molecule (hydroxyl ion) acts as a more effective nucleophile, thereby releasing acetate. The molecular interactions between OPs

and AChE (Figure 45.6) have been studied in much more detail than between CMs and AChE. The rates of hydrolysis and reactivation of AChE following carbamylation and phosphorylation of the active site appears to be markedly slower than for the hydrolysis of the acetylated enzyme. The turnover time for ACh is of the order of  $\sim 150 \mu\text{sec}$ , whereas the carbamylated enzyme  $t_{1/2}$  for hydrolysis is substantially slower ( $\sim 15\text{--}30 \text{ min}$ ). The phosphorylated enzyme is highly

FIGURE 45.4 Chemical structures of commonly used CM pesticides.

**FIGURE 45.5** Interaction of acetylcholine (I), the carbamate carbaryl (II), and the organophosphate chlorpyrifos-oxon (III) with the active site of acetylcholinesterase (AChE). The general rate of bound AChE hydrolysis is ACh > carbaryl > chlorpyrifos-oxon (Timchalk, 2006).

**FIGURE 45.6** Schematic drawing of the active site gorge of AChE, with the entry of an OP molecule. R<sub>1</sub> and R<sub>2</sub> on the OP are usually identical alkyl chains, whereas R<sub>3</sub> is the leaving group. The catalytic triad consists of Ser203, His447 and Glu334. The acyl binding site is likely important in positioning the inhibitor for the nucleophilic attack from Ser203 (Ordentlich *et al.*, 1996), whereas the oxyanion hole may polarize the P=O bond, thereby facilitating the nucleophilic attack (Ordentlich *et al.*, 1998). Binding of ligand to the peripheral anionic site can lead to inhibition or activation. Additionally, the peripheral anionic site plays an important role in the stereoselectivity of AChE toward methylphosphonates (Ordentlich *et al.*, 2004). Adapted from Sultatos (2006).

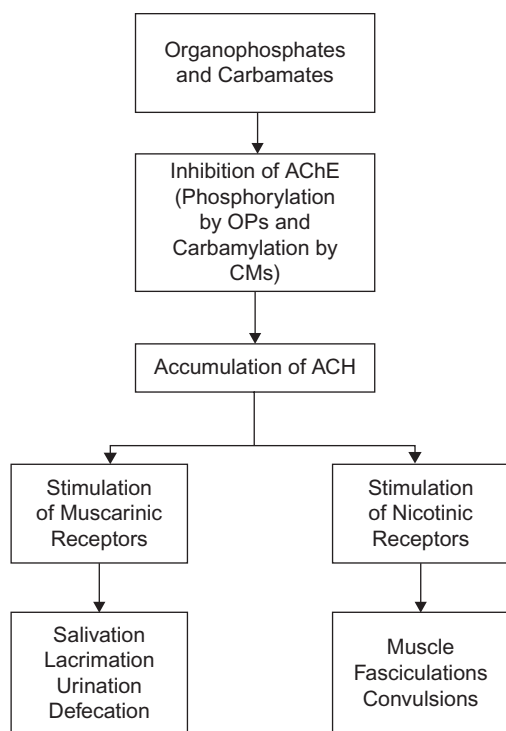

stable ( $t_{1/2}$  ~days), and further dealkylation of the phosphorylation group produces an “aged” AChE that is irreversibly inhibited (Taylor, 2006; Timchalk, 2006). In general, OPs and CMs are considered as irreversible

and reversible AChE inhibitors, respectively. Details of cholinesterases (ChEs), interaction of OPs and CMs with ChEs, and reactivation/regeneration of ChEs, are described elsewhere (Radic and Taylor, 2006; Sultatos, 2006; Timchalk, 2006; Jokanovic, 2010; Gupta and Milatovic, 2011).

By now, it is established that OP/CM-induced seizures and lethality are also associated with non-cholinergic mechanisms, such as *N*-methyl-*D*-aspartate (NMDA) receptors, and adenosinergic, gamma-aminobutynergic (GABA-ergic), and the monoaminergic systems (Gupta *et al.*, 2007; Dekundy and Kaminski, 2010; Myhrer, 2010; Gupta and Milatovic, 2011). Furthermore, the persistence of excitotoxicity for more than an hour can lead to oxidative and nitrosative stress, neuroinflammation and neurodegeneration in cortex, amygdala and hippocampus, which are the areas of brain primarily involved in initiation and propagation of convulsions and seizures.

## TOXICITY

Most animal poisoning cases in the field are acute in nature. Onset of clinical signs usually occurs within 15min to 1h, followed by signs of maximal severity. However, timings of maximal severity signs tend to

**FIGURE 45.7** Important steps involved in mechanism of toxicity of OPs and CMs.

vary depending upon the OP/CM compound and its dose, and species. For example, onset of clinical signs is delayed with chlorpyrifos (Dursban) and dimethoate (Rogor). Clinical signs observed in poisoned animals can be divided into local and systemic effects. The local effects involve the eyes and the lungs, owing to their exposure to vapors or droplets of the insecticides. These effects, however, are of significance in the case of animals only when exposure is via spraying. The systemic effects are primarily on the brain, skeletal muscles, lungs, heart and other organs.

The clinical signs can also be classified as muscarinic, nicotinic and central. Figure 45.7 describes the sequence of events involved in OP/CM toxicity. Muscarinic receptor-associated effects are manifested by vomiting, abdominal pain, salivation, lacrimation, urination, diarrhea (SLUD), miosis (pinpoint pupils), tracheobronchial secretion, lung edema and cyanosis. The nicotinic receptor-associated effects are produced on autonomic ganglia and skeletal muscles, and the affected animals show twitching of muscles, tremors, followed by convulsions and seizures. This condition may lead to paralysis. The central effects include apprehension and stimulation, followed by depression. The affected animals may also show restlessness, ataxia, stiffness of the neck and coma. Death occurs due to respiratory failure and cardiac arrest. It is important to mention that not all poisoned animals show all the clinical signs (as described

**TABLE 45.4** Normal acetylcholinesterase (AChE) activity in brain cortex of different species

Species	AChE ( $\mu\text{mol/g/h}$ )
Cattle	160
Swine	163
Sheep	170
Horse	124
Chicken	1098
Dog	200
Rat	255

above) with every OP or CM compound. Furthermore, at nonlethal doses, the signs of toxicity caused by each OP or CM can vary widely. This can be due to the fact that each OP or CM reacts not only with AChE but also with other targets, such as butyrylcholinesterase, carboxylesterases, neuropathy target esterase (NTE), acylpeptide hydrolase, arylformamidase, proteases, trypsin, chymotrypsin, cannabinoid CB1 receptor, albumin and many other enzymes, receptors and proteins (Gupta, 2004; Lockridge and Schopfer, 2006; Ruark *et al.*, 2011). While surviving animals usually recover within 3 to 6 h with CMs and within 24 h with OPs, animals exposed to OP nerve agents may show signs of toxicity for days.

Poisoning cases of OP or CM are usually diagnosed based on clinical signs and quantified levels of AChE inhibition in blood from a live animal and brain from a dead animal. Inhibition of AChE activity >70% is considered a positive case of poisoning. It should be noted that great species variability exists in normal values of AChE activity (Table 45.4). In addition, there is more than a six-fold variability in AChE activity in different brain areas with preference given to cortex and not the striatum for AChE analysis (Gupta, 2004). Therefore, interpretation should be made with great caution. Residue analysis of an insecticide and/or its metabolite(s), and by confirmation with GC/MS or LC/MS, seems an ideal approach for diagnosis.

## TREATMENT OF ACUTE POISONING

Before instituting antidotal therapy, monogastric animals, such as the dog, should be given gastric lavage. Animals of any species can be given activated charcoal to stop further absorption of insecticides. Animals should be washed thoroughly with water if they are exposed to insecticides dermally. Intravenous fluid therapy is always beneficial.

In the case of OP poisoning, antidotal treatment requires the combined use of atropine sulfate and pyridine-2-aldoxime methochloride (2-PAM). Atropine sulfate

acts by blocking the muscarinic receptors from ACh. In ruminants, one-fourth of the total recommended dose (0.5 mg/kg) can be given as a slow IV injection, and the remainder through IM or SC injection (Gupta, 1984). The total dose of atropine sulfate for an average size horse is about 65 mg, and for a dog is about 2 mg. Atropine sulfate treatment can be repeated at an interval of every hour until all hypersecretory signs have subsided. 2-PAM reactivates the AChE inhibited by OPs. The recommended therapeutic dose of 2-PAM is 20 mg/kg, IV. The injection of 2-PAM can be repeated once after 1 h at half of its initial dose. Care should be taken that only a freshly prepared solution of 2-PAM be used. It needs to be emphasized that the combined therapy of atropine sulfate and 2-PAM is superior to any other treatment till today in the case of OP poisoning. Although many other oximes have been tested against many OPs, none has been proven to be better than 2-PAM. Furthermore, the depressant drugs, such as morphine and barbiturates, are contraindicated, since they aggravate the condition. Diazepam without atropine sulfate also accentuates the toxicity of OPs.

Unlike with OP poisoning, 2-PAM and other oximes are ineffective in CM poisoning cases. In fact, in the case of some carbamates, such as carbaryl and carbofuran, 2-PAM therapy accentuates the toxicity. Some anticonvulsant drugs, such as barbiturates and diazepam, also aggravate the toxicity of CMs. Therefore, atropine sulfate, with doses as described for OPs, is the only preferred antidote. However, when the animals are exposed to very high doses of carbamates, atropine sulfate does not appear to be a life-saving antidote.

## OP-INDUCED INTERMEDIATE SYNDROME

OP insecticide-induced intermediate syndrome (IMS) was reported for the first time in human patients in Sri Lanka in 1987 (Senanayake and Karalliedde, 1987). The observations were made in ten patients who presented 24–96 h after acute cholinergic crisis from exposure to methamidophos, fenthion, dimethoate and monocrotophos. This syndrome has also been diagnosed in OP-poisoned patients in South Africa (1989), Turkey (1990), Belgium (1992), the United States (1992), Venezuela (1998), France (2000) and in many other countries. To date, OPs that are known to cause IMS include bromophos, chlorpyrifos, diazinon, dicrotophos, dimethoate, disulfoton, fenthion, malathion, methamidophos, methyl parathion, monocrotophos, omethoate, parathion, phosmet and trichlorfon. IMS is usually observed in individuals who have ingested a massive dose of an OP insecticide either accidentally or in a

suicide attempt. In 2005, a carbamate insecticide carbofuran was also demonstrated to cause IMS in patients accidentally or intentionally exposed to large doses of this insecticide (Paul and Mannathukkaran, 2005). IMS is clearly a separate clinical entity from acute toxicity and delayed polyneuropathy. Clinically, IMS is characterized by acute paralysis and weakness in the areas of several cranial motor nerves, neck flexors and facial, extraocular, palatal, nuchal, proximal limb and respiratory muscles 24–96 h after poisoning. Generalized weakness, depressed deep tendon reflexes, ptosis and diplopia are also evident. These symptoms may last for several days or weeks depending on the OP involved. A similar syndrome has also been observed in dogs and cats poisoned maliciously or accidentally with massive doses of certain OPs. It should be noted that despite severe AChE inhibition, muscle fasciculations and muscarinic receptor-associated hypersecretory activities are absent.

Although the exact mechanism involved in pathogenesis of IMS is unclear, studies suggest that decrease of AChE and nicotinic ACh receptor mRNA expression occur after oral poisoning with disulfoton in rats. Involvement of oxidative stress is also suggested (Dandapani *et al.*, 2003). Based on electromyographic (EMG) findings from OP-poisoned patients and experimental studies on laboratory animals, it has been found that the defect in IMS is at the neuromuscular endplate and postsynaptic level, but the effects of neural and central components in producing muscular weakness have not been ruled out. It seems clear that some OPs are greatly distributed to muscles and have higher affinity for nicotinic ACh receptors. Currently, very little is known about the type of damage at the motor endplate or about risk factors contributing to its development. There is no specific treatment, and therapy relies upon atropine sulfate and 2-PAM. The administration of atropine sulfate and 2-PAM should be continued for a long period, even if efficacy of these drugs on the development of IMS appears to be limited. For further details about IMS, readers are referred to Gupta (2005) and De Bleeker (2006).

## CHRONIC TOXICITY

Chronic toxicity is a major concern with OP pesticides. OP compounds that produce delayed neurotoxic effects are esters of phosphorus-containing acids. Over 40 years ago, tri-*o*-cresyl phosphate (TOCP) was known to produce delayed neurotoxic effects in man and chicken, characterized by ataxia and weakness of the limbs, developing 10 to 14 days after exposure (Johnson, 1969). This syndrome was called OP-induced delayed neuropathy (OPIDN). In recent literature, the syndrome

has been renamed OP-induced delayed polyneuropathy (OPIDP). OPIDP is characterized by distal degeneration of long and large-diameter motor and sensory axons of both peripheral nerves and spinal cord. Among all animal species the hen appears to be the most sensitive and therefore used as an animal model. TOCP and certain other compounds have minimal or no anti-AChE property; however, they cause phosphorylation and aging (dealkylation) of a protein in neurons called neuropathy target esterase (NTE), and subsequently lead to OPIDP. Studies on the sensitivity of the target enzymes of a variety of OPs showed that the comparative inhibitory power of OPs against hen AChE and NTE *in vitro* correlates with their comparative effects *in vivo* (i.e., delayed neuropathy or death). The relationship between the degree of NTE inhibition and the severity of OPIDP changes according to the compound involved and the source of NTE. For example, certain compounds cause OPIDP with a minimum of 70% NTE inhibition, while others require almost complete inhibition to cause OPIDP. Inhibition of peripheral nerve NTE is required to develop OPIDP and no clinical deficits appear if only brain NTE is inhibited. For neuropathy to occur, a second reaction called “aging” of NTE must take place and this involves cleavage of the lateral side chain from the phosphorylated NTE. This reaction is called aging because it is a slow progressive process and the product is no longer responsive to nucleophilic reactivating agents, such as oximes. The cascade of events from NTE inhibition/aging to impairment of retrograde axonal transport and axonal degeneration is yet to be explained (Moretto and Lotti, 2006). Today, many compounds, such as DFP, *N,N'*-diisopropyl phosphorodiamidic fluoride (mipafox), tetraethyl pyrophosphate (TEPP), parathion, *o*-cresyl saligenin phosphate and haloxon, are known to produce this syndrome. Some OPs as well as non-OP inhibitors (such as carbamates and sulfonyl fluorides) also covalently react with NTE but cannot undergo the aging reaction. As a result, these inhibitors do not cause OPIDP, and when given to experimental animals prior to neuropathic OP, may protect from OPIDP when they occupy at least 30% of the NTE active site. For the details of OPIDP syndrome, readers are referred to Morreto and Lotti (2006) and Wu and Chang (2010). Treatment of this syndrome is symptomatic.

## TOLERANCE DEVELOPMENT

Tolerance development to the toxicity of OPs was noted more than 50 years ago. Following prolonged exposure to an OP, the physiological effects often diminish more than expected from the degree of AChE inhibition or

repeated additions of OP give lower responses with time. Tolerance to AChE inhibiting OPs (such as DFP, disulfoton, methyl parathion and others) has been observed using different forms of administration and in different species, such as mice, rats, guinea pig and man (Fonnum and Sterri, 1981, 2006; Gupta and Dettbarn, 1986; Gupta *et al.*, 1986; Gupta, 2004).

Tolerance to OP toxicity can develop in several ways. Most often, it occurs due to receptor changes either in the number of receptors or by decreased affinity of the receptor molecule. However, it can also occur due to the presence of other proteins that can bind or inactivate the inhibitor and thereby make it less readily available. Some of the examples for binding to the OPs are carboxylesterases (CarbEs), butyrylcholinesterases (BuChEs) or other binding proteins such as albumin (Sogorb and Vilanova, 2010). In addition, tolerance can be achieved through more rapid metabolism of the OP compounds by OP-hydrolyzing enzymes such as paraoxonases (PONs) and somanases (Fonnum and Sterri, 2006).

ACh receptors (both mAChRs and nAChRs) are involved in the development of tolerance to OP toxicity. Treatment with a cholinergic agonist for a prolonged time leads to a decrease in the muscarinic ACh receptors (mAChRs). This is common for G protein-linked receptors. In some studies, OPs have been found to cause decrease in the numbers of mAChRs in the brain, while in others both the number of mAChRs and the affinity to the ligand in ileum and striatum.

Significant reductions in nAChRs numbers ( $B_{max}$ ), without change in affinity ( $K_D$ ), have been found in brain of tolerant rats treated with disulfoton (Costa and Murphy, 1983) and in skeletal muscle of rats treated with DFP (Gupta *et al.*, 1986; Gupta and Dettbarn, 1986). In tolerant rats, significant recovery of CarbEs and BuChEs has also been found. In essence, tolerance development following subchronic or chronic treatment with AChE inhibiting OPs occurs through multiple mechanisms.

## CONCLUSIONS AND FUTURE DIRECTIONS

OPs and CMs constitute a large number of chemicals that are used in agriculture primarily as insecticides and in veterinary medicine as parasiticides. These chemicals exert a broad range of toxic effects, varying from mild effects such as salivation and tremors to serious effects such as convulsions, seizures, paralysis and death. Basically, OPs and CMs are neurotoxicants, but directly or indirectly several vital organs are affected. These chemicals produce a variety of toxicological effects on the central nervous system, peripheral nervous system

and cardiovascular, pulmonary, ocular, neurobehavioral, immunological, reproductive, placental, cutaneous and other body systems. In addition, these insecticides cause neurodegeneration, oxidative stress, endocrine disruption and many other complications. In general, OPs produce more serious and lingering health effects than CMs. These devastating effects, including a complex syndrome like OPIDP, are yet to be mechanistically characterized and fully defined. It is expected that newer compounds of both OP and CM classes with greater selective toxicity as well as improved antidotes effective in patients with OPIDP or against CMs will be developed.

# Organochlorines

Steve M. Ensley

## INTRODUCTION

Many methods have been used and developed to control or eliminate insects and other plant and animal pests that have threatened man and his food supply. A few examples of chemicals used in the past to control insects are sulfur (used before 1000 BC and is still used today), vinegar, whale oil and arsenic (used in the 1500s), nicotine (used in the 1600s), rotenone from the plant *Derris elliptica*, pyrethrum from *Chrysanthemum cinerariaefolium*, copper arsenate (used in the 1800s) and calcium and lead arsenate (used in the early 1900s). There were major changes in the development and use of insecticides in the 1930s when the synthetic organic chemical industry began developing compounds to control insects. Chlorinated compounds, cyclodienes such as aldrin and dieldrin, used as insecticides, became available for use in the 1940s. Dichlorodiphenyltrichloroethane (DDT) became available during WWII and was used extensively as an insecticide worldwide. One of the reasons that organochlorines were effective insecticides was their ability to persist in the environment (Leonard *et al.*, 1999; Hites *et al.*, 2004; Hoekstra *et al.*, 2005). Because of that persistence, most have been eliminated from use today. Lindane (gamma-hexachlorocyclohexane) and endosulfan are the most biodegradable organochlorines and are still used today.

The diphenyl aliphatic organochlorines, such as DDT, affect the peripheral nerves and brain by slowing sodium ( $\text{Na}^+$ ) influx and inhibiting potassium ( $\text{K}^+$ ) outflow. This results in excess intracellular  $\text{K}^+$  in the neuron, which partially depolarizes the cell.

In the 1980s, the mechanism of toxicity for the cyclodiene organochlorine insecticides was determined. These

compounds were found to be non-competitive antagonists acting on the chloride ion channel of the gamma-aminobutyric acid A (GABA) receptor.

## BACKGROUND

Even though DDT was first synthesized by Othmar Zeidler in 1874, it was another 40 years before this compound was used as an insecticide. Paul Mueller, a Swiss chemist, rediscovered DDT in 1939 while investigating insecticides for use against clothes moths and carpet beetles. Mueller won the Noble Prize in 1948 for this work. "This pleasant smelling, greasy white powder (DDT) has had an influence on human ecology perhaps unmatched by any other chemical discovery including gunpowder, sulfanilamide, penicillin, and plutonium" (Metcalf, 1973).

The insecticidal properties of technical HCH (t-hexachlorocyclohexane; commonly known as benzene hexachloride) and the first cyclodiene insecticides (e.g., aldrin, dieldrin, chlordane) were discovered as a result of the commercial interest in new uses for chlorine and hydrocarbons such as cyclopentadiene and benzene. The first use of the chlorinated hydrocarbons was for dielectrics and as fire retardants. The use of these compounds as insecticides occurred when benzene was added to liquid chlorine in the field and it was noted that the product killed insects.

As with many insecticides there are many unintended secondary targets for every insecticide (Uzoukwu and Sleight, 1972; Furie and Trubowitz, 1976; Hathway, 1977). The following is a brief discussion about the

organochlorines and some of the intermediates used in their production. Hexachlorocyclopentadiene, a raw material used in manufacturing chemicals, was known to be stable and was found to react easily with cyclopentadiene in a Diels-Alder reaction, which leads to the production of chlordane. It was discovered later to react with norbornadiene (a bicyclic hydrocarbon) to produce aldrin. Allylic chlorination of chlordane produces heptachlor. The intermediate hexachloronorbornadiene (HCNB) reacts with cyclopentadiene to produce isodrin and after epoxidation, dieldrin and endrin are produced. Technical hexachlorocyclohexane (t-HCH) can be used to produce the gamma isomer lindane. One of the problems with the production of lindane is the inefficiency of the process; for every ton of lindane produced, 8–10 tons of the inactive alpha and beta isomers are formed. Because of the widespread use of t-HCH, the environment has become contaminated with the inactive alpha and beta-HCH isomers.

Overcoming the problem of insect resistance to the organochlorines has also been associated with toxicity. A major mechanism of insect resistance to DDT was found to be enzymatic dechlorination of DDT to dichlorodiphenyldichloroethylene (DDE) (Bonner and Yarbrough, 1988). While working to overcome resistance to DDT, it was discovered that certain nontoxic DDT analogs and other compounds suppressed resistance when co-applied with DDT. Toxicity to parent compounds as well as congeners has been associated with use of the organochlorines.

The beginning of the science of toxicology can be traced to the problems associated with use of DDT and the subsequent impact on man and the environment. Rachel Carson's book *Silent Spring* brought the problems associated with the use of DDT to national attention in 1962. Organochlorines continue to be an environmental contaminant as evident in this 2010 study (Ding *et al.*, 2010).

The structures of various organochlorine insecticides are shown in Figure 46.1.

## PHARMACOKINETICS/ TOXICOKINETICS

Organochlorine insecticides can be absorbed orally and topically, with absorption being rapid due to the lipid solubility of these compounds (Buck *et al.*, 1976; Marth *et al.*, 1989). Organochlorine insecticides are not highly volatile, so inhalation is not a normal route of exposure (Jaeger *et al.*, 1973). Distribution is to the liver, kidney, brain and adipose tissue (Buck and Van Note, 1968; Buck, 1970; Booth and McDowell, 1975). The acute toxicity caused is of concern, but bioaccumulation from chronic

FIGURE 46.1 Structures of common organochlorines.

exposures is equally important (Starr and Clifford, 1972). Chlorinated hydrocarbons are highly lipid soluble and persist in the environment; as a result bioaccumulation occurs in the food chain from the environment to animals and humans (Mount *et al.*, 1980; Oehme, 1991; Safe and Krishnan, 1995; Watanabe *et al.*, 1999; Backer *et al.*, 2001; Smith and Gangolli, 2002; Harris *et al.*, 2005).

As with all xenobiotics, the toxicity of the organochlorines is related to absorption, distribution, metabolism and elimination (Jaeger *et al.*, 1975; Beasley *et al.*, 1994). The diphenyl aliphatics, such as DDT, are dechlorinated by mixed function oxidases (MFOs). Aryl hydrocarbons, like paradichlorobenzene, undergo glucuronidation and sulfation. The cyclodiene insecticides, such as endrin, are rapidly converted to epoxides by MFOs. Methoxychlor is rapidly eliminated compared to DDT by dechlorination and oxidation. The intermediates of organochlorine insecticide production may be more toxic than the parent compound.

The major excretory route of organochlorines is from bile into the digestive tract, and as a result enterohepatic recycling can occur. Metabolites are also lipophilic, will move into adipose tissue and are released slowly from lipid depot storage (Sell *et al.*, 1977). The half-life of some diphenyl aliphatics, such as DDT and the cyclodienes, may range from days to years (Council for Agricultural Science and Technology, 1974). Elimination can sometimes be explained by a two-compartment model, where the first phase is rapid elimination and the second is prolonged.

## MECHANISM OF ACTION

There are at least two different mechanisms of action for organochlorine insecticides (Shankland, 1982; Narahashi, 1987; Osweiler, 1996). DDT-type organochlorine (dichlorodiphenylethanes) insecticides affect the peripheral nerves and brain by slowing sodium ( $\text{Na}^+$ ) influx and inhibiting potassium ( $\text{K}^+$ ) efflux. This results in excess intracellular  $\text{K}^+$  in the neuron, which partially depolarizes the cell. The threshold for another action potential is decreased, resulting in premature depolarization of the neuron.

The aryl hydrocarbons and cyclodienes, in addition to decreasing action potentials, may inhibit the postsynaptic binding of GABA (Bloomquist and Soderlund, 1985; Lummis *et al.*, 1990; French-Constant, 1993; Hahn, 1998; Carr, *et al.*, 1999). The cyclodiene organochlorine insecticides act by competitive inhibition of the binding of GABA at its receptor, causing stimulation of the neuron, as described below (Joy, 1976, 1982; Gandolfi *et al.*, 1984).

GABA is a neurotransmitter in the mammalian and insect central nervous system and the inhibitory neurotransmitter for insects at the neuromuscular junction.  $\text{GABA}_\text{A}$  receptors, present in mammalian and insect synapse, are ligand gated chloride ion channels. In mammals,  $\text{GABA}_\text{B}$  receptors are coupled to calcium and potassium channels and the action of GABA is mediated by G-proteins.  $\text{GABA}_\text{B}$  receptors are not important in insect physiology. When GABA is released in the synapse it diffuses to the presynaptic terminal of another nerve, where it binds to a  $\text{GABA}_\text{A}$  receptor. This causes chloride ions to enter the synapse resulting in hyperpolarization of the terminal and inhibition of release of other neurotransmitters. Because of this inhibition, post-synaptic stimulation of other nerves by other transmitters (e.g., acetylcholine) is reduced. When GABA is inhibited, there is no synaptic down-regulation and other neurotransmitters can be released in excess. The inhibitory mechanism of GABA explains the cholinergic effects (over stimulation by acetylcholine) of dieldrin and lindane on some species.

TABLE 46.1 Toxicity data for some organochlorines

Compound	Rat acute oral $\text{LD}_{50}$ (mg/kg)	Rabbit dermal $\text{LD}_{50}$ (mg/kg)
Lindane	76–190	500
Aldrin	39–60	65
Dieldrin	40	65
Endrin	3	12
Chlordane	283–1100	580
Endosulfan	18–76	74
Mirex	235–>3000	800
Kepone	95–125	345
Toxaphene	40–127	600

FIGURE 46.2 Illustration of the  $\text{GABA}_\text{A}$  receptor of the mammalian brain. The  $\text{M}_2$  segments form the chloride ion channel (McDonald and Olsen, 1994).

## TOXICITY

Cats are the most sensitive species to organochlorine insecticides, with the  $\text{LD}_{50}$  for endrin in cats of 3–6 mg/kg. The cyclodiene organochlorine insecticides cause more seizure activity and have a lower  $\text{LD}_{50}$  than the DDT-type insecticides in most species.

The oral  $\text{LD}_{50}$  for DDT in rats is 113–2500 mg/kg and the IV  $\text{LD}_{50}$  is 47 mg/kg. In humans, toxic signs from oral exposure to organochlorines can be observed at 10 mg/kg.

The acute toxicity to rats and the housefly of other chlorinated insecticides is shown in Table 46.1.

A description of the  $\text{GABA}_\text{A}$  receptor in the human brain is presented in Figures 46.2 and 46.3 to clearly describe the chloride ion channel. The  $\text{GABA}_\text{A}$  receptor of the human brain consists of four or five 50–60 kDa glycoprotein subunits, each of which contains four ( $\text{M}_1$ – $\text{M}_4$ ) hydrophobic domains. The five  $\text{M}_2$  domains are arranged to form a 5.6 Å diameter ion channel.

**FIGURE 46.3** Illustration of the GABA<sub>A</sub> receptor of the mammalian brain (McDonald and Olsen, 1994).

In addition to the effects on the nervous system, DDT metabolites can inhibit the output of the adrenal gland by selective necrosis of the zona fasciculata and the zona reticularis.

Following an acute or chronic exposure, organochlorines can produce a variety of reproductive and developmental effects in animals as well as humans (Gupta, 2009; Malik *et al.*, 2011). Chronic exposure to DDT has been documented to cause eggshell thinning and reduced fertility in wild birds.

## TREATMENT

No specific antidotes for organochlorine insecticides are available (Osweiler, 1996). Detoxification is the most essential component of therapy for organochlorine toxicity. If dermal exposure has occurred, the animal should be thoroughly washed with a detergent and water to remove the insecticide so absorption ceases. The hair of heavily contaminated long haired animals should be clipped. Personnel treating animals should exercise caution and prevent themselves from becoming contaminated with the insecticide by wearing gloves, aprons or raincoats.

For oral exposure to organochlorines, activated charcoal (1–2 g/kg) should be administered orally. An alternative but less effective treatment is mineral oil. The insecticide can dissolve in mineral oil, which decreases its absorption systemically. The approximate oral dose of mineral oil is 2–6 ml in cats, 5–15 ml in dogs and 1–3 liters in large animals. Charcoal or nonabsorbable oils are most effective when given within 4 hours of ingestion of the pesticide (Aslani, 1996).

General supportive care includes the use of antiseizure medications such as diazepam, phenobarbital or pentobarbital. Animals should be placed in a warm and comfortable area to minimize trauma when they are seizing. Animals recovering from organochlorine insecticide exposure may have to be monitored long term because organochlorines can persist in the body for months or years. The source of the exposure must be identified and removed to stop exposure. One decontamination strategy is to reduce feed intake so that the animal loses body fat, thereby reducing organochlorine residues in adipose tissue. Lactating animals rapidly eliminate organochlorine residues because the residues are excreted in milk. An additional treatment option in large animals is to feed activated charcoal (500–1000 g/day) to reduce enterohepatic recycling.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

The use of organochlorine insecticides is decreasing in the United States but they are still used worldwide. In the United States, with the ability of these compounds to persist in the environment and bioaccumulate, the organochlorine insecticides will continue to be an important toxicant for many years (Custer *et al.*, 2005).

## Pyrethrins and pyrethroids

Steve M. Ensley

### INTRODUCTION

Pyrethrins are the insecticidal compounds obtained from the flowers of the plant *Tanacetum cinerariaefolium*, also called *Chrysanthemum cinerariaefolium* or *Pyrethrum cinerariaefolium*. Pyrethrum denotes extracts from the flowers that contain the active pyrethrin compounds (Proudfoot, 2005). The use of pyrethrum in insecticide preparations dates back to Persia, about 400 BC. Pyrethroids are synthetic analogs of pyrethrins. Because of stability problems with the natural pyrethrins, these insecticides were replaced by the more stable organophosphate and organochlorine insecticides developed after World War II (Valentine, 1990). As a result of the toxicity and environmental contamination associated with the organophosphate and organochlorine insecticides, interest in the use of pyrethrins and pyrethroids re-emerged in the 1970s. Pyrethrin and pyrethroid insecticides are effective against a variety of insect pests on companion animals and livestock, and are used on farms, in the home and garden and have many public health applications because of the safety associated with these compounds.

### BACKGROUND

There are six compounds that comprise the natural pyrethrins; pyrethrin I and II, jasmolin I and II and cinerin I and II. Synthetic pyrethroids have been developed because the natural pyrethrins tend to break down quickly when exposed to air, light and heat. The synthetic pyrethroids can be classified as first and second

generation. First generation pyrethroids are esters of chrysanthemic acid and an alcohol, having a furan ring and terminal side chain moieties. Second generation pyrethrins have 3-phenoxybenzyl alcohols derivatives in the alcohol moiety, and have had some of the terminal side chain moieties replaced with a dichlorovinyl or dibromovinyl substitute and aromatic rings. Addition of the alpha-cyano group to the 3-phenoxybenzyl alcohol group in the second generation pyrethroids has increased the insecticidal potency.

Pyrethrins cause hyperexcitability with very little cytotoxicity. The molecular targets of the pyrethrins and pyrethroids are similar in mammals and insects and include voltage-gated sodium, chloride and calcium channels, GABA-gated chloride channels, nicotinic receptors, membrane depolarization and intercellular gap junctions (Forshaw and Ray, 1990; Song and Narahashi, 1996a). Mammals are less susceptible to pyrethrin and pyrethroid toxicoses than insects primarily because they have a faster metabolic clearance, higher body temperatures and a lower affinity for the pyrethrins/pyrethroids (Song and Narahashi, 1996b) (Figure 47.1).

### PHARMACOKINETICS/ TOXICOKINETICS

Determination of the toxicity of pyrethroids *in vivo* is difficult because they have low water solubility, easily partition into lipids and will bind to plastics and glass. The reported toxicity of this class of insecticides has high variability.

FIGURE 47.1 Structures of selected pyrethrins and pyrethroids.

Most pyrethrin and pyrethroid products are applied dermally in animals, but because of grooming, there can be oral and inhalation exposures, too. Less than 2% of topically applied pyrethrin and pyrethroid insecticides are absorbed dermally (Wollen *et al.*, 1992). One study confirmed that absorption of cypermethrin across human skin is minimal and peak excretion rates

after dermal application were not observed until 12 to 36 hours after dosing. Pyrethrins may be sequestered in the skin and slowly released into the systemic circulation (He *et al.*, 1989). Oral or inhalation exposure results in faster systemic exposure (Anadon *et al.*, 1996). Approximately 40–60% of an orally ingested dose is absorbed. When cypermethrin was administered orally

to six adult male volunteers, oral absorption ranged from 27 to 57% of the administered dose and peak excretion rates were measured in the urine between 8 and 24 hours after dosing. When adult males were exposed to cyfluthrin at  $160\mu\text{g}/\text{m}^3$ , 93% of the metabolites were excreted within the first 24 hours with peak excretion rates ranging from 0.5 to 3 hours.

Pyrethroids are lipophilic and will distribute to tissues with high lipid content such as fat and nervous tissue in addition to liver, kidney and milk. Recently, Kim *et al.* (2008) described the pharmacokinetics and tissue distribution of deltamethrin in adult rats following oral or intravenous administration. Utilizing a physiologically based toxicokinetic model, GI absorption of deltamethrin was rapid, but bioavailability was low. Deltamethrin in blood was largely present in plasma. A very small proportion of the absorbed doses reached or remained in the brain. Fat, skin and muscle ultimately accumulated large amounts of this highly lipophilic insecticide.

Pyrethroids and pyrethrins are rapidly hydrolyzed in the gastrointestinal tract. Once absorbed these compounds are metabolized by mixed function oxidases and esterases. Metabolism of the pyrethroids results in water soluble metabolites. Metabolism includes hydrolysis of the central ester bond, oxidation at several sites and conjugation with glycine, sulfate, glucuronide or glucosides. Cleavage of the ester bond results in substantial reduction in toxicity. The presence of the alpha-cyano group, as in type II pyrethroids, will decrease the rate of hydrolysis of the ester bond. Cleavage of the alpha-cyano group results in rapid conversion of the cyano group to thiocyanate.

Pyrethroids are eliminated by first order kinetics and most of the dose is eliminated in the first 12–24 hours after absorption. The primary routes of excretion are urinary and fecal, as a mix of parent compound and metabolites.

## MECHANISM OF ACTION

Pyrethroids primarily affect the sodium channel of cells, but chloride and calcium channels are also affected. Pyrethrins and pyrethroids slow the opening and closing of the sodium channels, resulting in excitation of the cell (Marban *et al.*, 1989; Conley and Brammar, 1999). The increase of sodium in the sodium channels results in a cell that is in a stable, hyperexcitable state. The duration of the sodium action potential is much longer for type II pyrethroids than for type I. Type I pyrethroids result in primarily repetitive charges with membrane depolarization predominating in type II pyrethroids. Paresthesia results from the direct action of pyrethroids on sensory

nerve endings, causing repetitive firing of these fibers. Less than 1% of sodium channels must be modified by pyrethroids to produce neurological signs. High concentrations of type II pyrethroids may also act on GABA-gated chloride channels (Bloomquist *et al.*, 1986).

Pyrethrins also affect the voltage-dependent chloride channels. These channels are found in the brain, nerve, muscle and salivary gland and control cell excitability. There are many different functional types of chloride channels in contrast to sodium channels. Most pyrethroid-sensitive channels belong to the Maxi chloride channel class. Maxi channels are activated by depolarization, have high conductance, are calcium independent and are activated by protein kinase C phosphorylation. Pyrethroids cause a decrease in the Maxi chloride channel current, which increases excitability of the cell just as the action of pyrethroids on the sodium channel.

The decreased sensitivity of mammals to this class of compounds compared to insects is due to several factors. Pyrethroids bind more strongly with the sodium channel at low temperatures than at high temperatures. Insects' ambient temperature is approximately  $25^\circ\text{C}$  compared to mammals at  $37^\circ\text{C}$ . Mammalian sodium channels are at least 1000 times less sensitive to pyrethroids than insect sodium channels. Mammalian sodium channels recover much more quickly from depolarization than do insect sodium channels and are much more likely to detoxify pyrethroids before they reach their target site than are insects.

Pyrethroids cause a phenomenon in insects called "knockdown" (Narahashi, 1985). Knockdown is caused by inhibiting the cell but not causing a lethal effect. This is caused from the ability of the sodium channels to retain many of the normal functions, such as selectivity for sodium ions and conductance after exposure to pyrethroids. After exposure to moderate doses of pyrethroids, cells function in a new state of hyperexcitability. If the level of sodium in the ion channel does not exceed the ability of the sodium pump to remove it, the cell continues to function normally. High concentrations of pyrethroids or hyperactivity beyond what the cell can sustain will cause depolarization and conduction block. The pyrethroids that hold the sodium channel open the longest will cause the greatest amount of depolarization.

There is marked stereospecificity of the action of pyrethroids on the sodium channel; some isomers are more toxic than others (Soderlund, 1985, 2012; Meacham *et al.*, 2008). The *cis* isomers are usually more toxic than the *trans* isomers. As an example, the 1*R* and 1*S* *cis* isomers bind competitively to one site, and the 1*R* and 1*S* *trans* isomers bind noncompetitively to another (Narahashi, 1986). In mammals the 1*R* isomers are active and the 1*S* isomers inactive, making the 1*S* isomers non-toxic. Deltamethrin has been produced using stereospecificity to produce a high degree of selective toxicity. This is the reason that the toxicity of different batches of

pyrethroids can vary from batch to batch. The rat oral LD<sub>50</sub> of commercial permethrin can vary from 430 to 8900mg/kg, with toxicity depending on the amount of *cis* isomer present in the batch.

TOXICITY

Dermal exposure to pyrethroids is most common (Osweiler, 1996). In humans, the bioavailability of pyrethroids applied dermally is approximately 1%. Absorption after oral exposure in humans is 36%, mostly from the stomach. Once absorbed, the pyrethroids are rapidly distributed due to their lipophilicity. Systemic distribution produces effects that can be difficult to control and may be confused with poisoning by other pesticides, such as organophosphates which also cause increased salivation and hyperexcitability. Many pyrethroid formulations also contain solvents which can also cause toxicity. Cats are very sensitive to pyrethroid exposure (Meyer, 1999; Malik *et al.*, 2010).

The half-life of pyrethroids in general in plasma is in hours, while oral exposure can be equally short. Cyfluthrin has a plasma half-life of 19–86 minutes. Intravenous LD<sub>50</sub>s for pyrethroids range from 0.5 to 250mg/kg. The major neurotoxicity observed in adults with pyrethroid toxicity is acute toxicity with no chronic or cumulative toxicity being caused. The excitatory motor signs are generated at the spinal level.

Fish are highly sensitive to pyrethrin and pyrethroid products, and contamination of lakes, streams, ponds or any aquatic habitat should be avoided (Bradbury and Coats, 1986, 1989; Ansari and Kumar, 1988). Household exposure of fish can occur when the premise is sprayed or fogged with insecticides and the aquarium aerator is left on. The tank and aerator should be covered during use of insecticides and the home should be well ventilated before uncovering and starting the pump.

Most avian species are thought to be tolerant of pyrethrin and pyrethroid products but carriers or propellants in spray formulations may be hazardous (Bradbury and Coats, 1982). There is very little literature about pyrethrin or pyrethroid toxicity of exotic avian species, reptiles or lagomorphs.

Tables 47.1 and 47.2 reference the oral toxicity of some type I and II pyrethroids.

In dogs, cats and large animals the clinical signs are similar for both type I and II compounds. Clinical signs include salivation, vomiting, hyperexcitability, tremors, seizures, dyspnea, weakness, prostration and death (Murphy, 1996). In rats with type I toxicity there is an increased response to stimulation, muscle tremors, excitement and paralysis (Beasley *et al.*, 1994). These

TABLE 47.1 Toxicity of selected type I pyrethroids

Type I compounds	Oral LD <sub>50</sub> (mg/kg body wt.) in rat
Pyrethrin I	900
Allethrin	680
Tetramethrin	4640
Resmethrin	100
Permethrin	2000

TABLE 47.2 Toxicity of selected type II pyrethroids

Type II compounds	Oral LD <sub>50</sub> (mg/kg body wt.) in rat
Cypermethrin	500
Deltamethrin	31
Fenvalerate	450
Fluvalinate	1000

clinical signs can also be compatible with strychnine toxicities. Type II overexposure will cause increased salivation, weakness and choreoathetosis. The concomitant use of pyrethrins and pyrethroids with synergists such as piperonyl butoxide, organophosphorus compounds or carbamates may increase toxicity by mechanisms involving inhibition of microsomal oxidation (Anadon *et al.*, 2009).

These insecticides can also produce cardiotoxic, neurobehavioral, reproductive and developmental effects in animals and humans (Vijverberg and van den Bercken, 1990; Wolansky and Harril, 2007; Gupta, 2009; Malik *et al.*, 2011).

TREATMENT

There is no specific antidote for pyrethroid toxicity; animals should be treated symptomatically. The main treatment for dermal exposure is to wash the animal with a mild detergent and water. Do not use any shampoos that contain additional insecticides as this could increase exposure to insecticides. Large and small animals should be treated the same. The pyrethroids bound to the skin cannot be removed by washing with soap and water, but dermal paresthesia can be reduced by applying corn oil to the site(s) of application. For oral exposure, emetics or gastric lavage can be used to empty the stomach, if within 1–2 hours of ingestion. Activated charcoal and a saline or sorbitol cathartic will reduce oral absorption and increase elimination.

Supportive therapy using diazepam or barbiturates to control hyperexcitability or seizures can be used. Phenothiazine tranquilizers should not be used because

they can lower the threshold for seizures. Atropine can be used to control excess salivation or gastrointestinal hypermotility.

The prognosis for pyrethroid toxicity is usually good because of the low toxicity.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

Pyrethroid insecticides, being of plant origin, are attractive to people that prefer to use organic insecticides on their companion animals or livestock, or who are engaged in organic food production. Pyrethrin insecticides, while toxic to selected species, have a wider margin of safety than organophosphate or organochlorine insecticides. Biomarkers of exposure to pyrethroids are being investigated. Urine is the matrix that is being most heavily investigated to determine which metabolites can be used to identify exposure to the parent compound. Advances in analytical methods to detect low concentrations of the pyrethroid metabolites will allow improved assessment of exposure in the future.

# Neonicotinoids

Steve M. Ensley

## INTRODUCTION

Neonicotinoids are a new class of insecticides with widespread use in veterinary medicine and crop production. The neonicotinoid insecticides include imidacloprid, acetamiprid, dinotefuran, thiamethoxam and clothianidin. In the last decade neonicotinoid insecticides have been the fastest growing class of insecticides in modern crop protection because of the widespread use against a broad spectrum of sucking and certain chewing pests (Jeschke *et al.*, 2010). Neonicotinoids have a relatively low risk for nontarget organisms and the environment, a high target specificity to insecticide and versatility in application methods (Cresswell, 2011). The neonicotinoids have been implicated in the Colony Collapse disorder in bees but this has not been proven.

Imidacloprid is a neonicotinoid compound that is used as an insecticide for dermal application on animals, for termite and grub control and as an insecticide for crop protection. The neonicotinoids act on nicotinic receptors in insects and vertebrates. To reduce toxicity to mammals and increase toxicity to insects, neonicotinoid compounds have been selected that are highly specific for subtypes of nicotinic receptors that occur in insects. The neonicotinoids do not readily pass the blood–brain barrier, further reducing the potential for mammalian toxicity (Yamamoto *et al.*, 1995). When administered orally, imidacloprid is rapidly absorbed, metabolized primarily in the liver and excreted primarily in urine. Imidacloprid does not accumulate in the body, and it is not carcinogenic, mutagenic, teratogenic nor a reproductive toxicant. Imidacloprid has a high margin of safety due to the high insecticidal specificity and low mammalian toxicity (Nagata *et al.*, 1999).

## BACKGROUND

The neonicotinoids were developed in the late 1970s by chemists at Shell Chemical Company doing research with the heterocyclic nitromethylenes for use as insecticides (Soloway *et al.*, 1978; Schroeder and Flattum, 1984). The neonicotinoids and chloronicotinyls are a separate class of compounds from the nicotinoids (Tomizawa and Yamamoto, 1993). Chemists at Nihon Bayer Agrochem discovered imidacloprid in 1984 when the 3-pyridylmethyl group was added to the nitromethylene heterocyclic parent molecule. This addition to nitromethylene greatly increased the insecticidal activity and reduced mammalian toxicity. After imidacloprid was discovered several other analogs with the 6-chloro-3-pyridylmethyl moiety have been developed, such as acetamiprid, nitenpyram and thiacloprid (Takahashi *et al.*, 1992; Minamida *et al.*, 1993; Yamada *et al.*, 1999). Figure 48.1 shows the structure of imidacloprid.

## PHARMACOKINETICS/ TOXICOKINETICS

There are two routes of imidacloprid metabolism in mammals. The first route of metabolism involves oxidative cleavage of imidacloprid to imidazolidine and 6-chloronicotinic acid. The imidazolidine moiety is excreted in the urine. The 6-chloronicotinic acid is further degraded by glutathione conjugation to a derivative of mercapturic acid, then to methyl mercaptonicotinic acid. The mercaptonicotinic acid is then conjugated

FIGURE 48.1 Structure of imidacloprid.

with glycine to form a hippuric acid conjugate that is excreted. A second route of metabolism involves hydroxylation of the imidazolidine ring followed by elimination of water and formation of an unsaturated metabolite. Specific information on the toxicokinetics of the rat can be found in [Thyssen and Machemer \(1999\)](#).

The following studies were conducted by Bayer CropScience ([Sheets, 2001](#)). Acute oral toxicity of imidacloprid in rats has been demonstrated at doses above 300 mg/kg with 100% mortality at 500 mg/kg. At doses in rats above 300 mg/kg, clinical signs were observed with 15 minutes of dosing and recovery was observed within 8 to 24 hours. A subchronic 13-week oral dosing study of imidacloprid in rats also demonstrated toxicity at a dose of 300 mg/kg in male rats. At a dose of 300 mg/kg in male rats, hypertrophy of hepatocytes and sporadic cell necrosis was observed in the liver. This mild liver damage was not observed after a 4-week recovery period. Serum alkaline phosphatase and alanine aminotransferase were elevated in male and female rats treated at 300 mg/kg and above. In dogs, a 13-week oral dose of imidacloprid at 15 mg/kg and above produced a tremor that increased with dose. A 52-week study in dogs at oral doses up to 72 mg/kg/day of imidacloprid did not produce tremors. The no observed effective level (NOEL) for this chronic oral exposure dog study was 15 mg/kg. Carcinogenicity was not observed in rats dosed orally at doses up to 103 mg/kg for 2 years. Studies confirm that imidacloprid is non-mutagenic, non-embryotoxic and non-teratogenic.

The most common adverse effects observed with dosing of neonicotinoids at low levels is decreased activity and tremors, impaired pupillary function (dilated or pinpoint pupils) and incoordinated gait; hypothermia is observed at higher doses. At lethal doses, deaths are observed within 4 hours of dosing. If death did not occur, recovery was observed within 8 to 24 hours of dosing.

## MECHANISM OF ACTION

Absorption and distribution of imidacloprid in rats occurs within 1 hour following oral administration. In rats more than 90% of a dose of imidacloprid is

eliminated within 24 hours. Approximately 80% of the dose is excreted by the urine with the remainder eliminated in the feces. Imidacloprid is not distributed to the central nervous system, fatty tissues or bone. This indicates that the blood-brain barrier allows little distribution to the central nervous system for imidacloprid in particular and the neonicotinoids in general.

The neonicotinoids act on post-synaptic nicotinic receptors ([Buckingham \*et al.\*, 1997](#)). These receptors are located entirely in the central nervous system of insects. Imidacloprid acts on at least three different subtypes of nicotinic receptors in the cockroach. Neonicotinoids cause a bi-phasic response: an initial increase in the frequency of spontaneous discharge followed by a complete block to nerve propagation. Insecticidal activity is increased by adding synergists that inhibit oxidative degradation ([Liu and Casida, 1993](#)).

Mammalian tissue also contains multiple subtypes of nicotinic receptors. The various subtypes are formed from different combinations of nine  $\alpha$ , four  $\beta$ ,  $\gamma$ ,  $\delta$  and  $\epsilon$  subunits ([Tomizawa \*et al.\*, 1999](#)). Nicotinic receptors in mammals are located in the autonomic ganglia, skeletal muscle, spinal cord and in different regions of the brain. Neonicotinoids have much lower activity in vertebrates compared to insects due to the different binding properties of the various receptor subtypes ([Yamamoto \*et al.\*, 1998](#); [Tomizawa and Casida, 2011](#)). Acute toxicity of the neonicotinoids in mammals is related to the potency at the  $\alpha_7$  nicotinic receptor subtype with the activity at the  $\alpha_4$ ,  $\beta_2$ ,  $\alpha_3$  and  $\alpha_1$  receptors having a decreasing effect on toxicity. Toxicity in mammals involves complex interactions at multiple receptor sites with some of the receptor types even having a combination of agonist and antagonist effects on the synapse.

## TREATMENT

There is no specific antidote to treatment of overdoses of imidacloprid. Treatment is symptomatic. If the exposure is dermal, washing the affected animal with soap and water is indicated. If the exposure is oral, emetics, adsorbents or cathartics could be used depending on whether vomiting is occurring spontaneously or not. Absorption and elimination of imidacloprid is rapid so immediate supportive care should allow for rapid recovery.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

The neonicotinoids have a wide safety margin in mammals and the insecticidal activity can be targeted so this class of compounds can have wide future use as an insecticide.

# Amitraz

Ramesh C. Gupta

## INTRODUCTION

Amitraz is a triazapentadiene compound, which is a member of the formamidine pesticide family. It has a chemical formula of  $C_{19}H_{23}N_3$  and molecular weight 293.41. Its chemical structure is shown in [Figure 49.1](#). Amitraz is commonly used in agriculture and horticulture as an insecticide and acaricide to control red spider mites, leaf miners, scale insects, aphids and other infestations. Amitraz is currently approved in the United States for various applications, including use on both food producing and companion animals. It is used to control ticks, mites, lice and many other pests on dogs, sheep, cattle and pigs. Amitraz is available as a wettable or pour-on powder, an emulsifiable liquid and a spray. It is also used as an active ingredient in formulations with other insecticides, such as metaflumizone (ProMeris®). Amitraz is sold under various product names, including Aazdieno, Acadrex, Acarac, Adrizan, Aludex, Amitik, Amitraze, Avartin, Baam, Bumetran, Ectodex, Edrizan, Kenaz, Mitac, Maitac, Metaban, Mitaban, Preventic, Ridd, Tickoff, Taktic, Triatix, Ovasyn, Ovidrex and many others. Of course, Mitaban, Preventic and Taktic are the three most popular brand names for amitraz. Amitraz poisoning is frequently encountered in dogs and cats ([Grossman et al., 1993](#); [Gunaratnam et al., 1993](#); [Hugnet et al., 1996](#); [Andrade et al., 2004](#)). In humans, poisoning occurs due to widespread use of amitraz veterinary products ([Ertekin et al., 2002](#); [Proudfoot, 2003](#); [Yilmaz and Yildizdas, 2003](#); [Aagin et al., 2004](#); [Avsarogullari et al., 2006](#)). Amitraz is not recommended for use in cats and horses as it causes toxicity. This chapter describes the toxicity of amitraz in animals with a special focus on dogs and cats.

## BACKGROUND

Amitraz is a broad spectrum insecticide and acaricide used in veterinary medicine and in agriculture and horticulture throughout the world since 1974. Amitraz has rapid action on the control of animal ectoparasites, such as mites, ticks, lice, etc., and it persists on hair and wool long enough to control all stages of the parasite. Amitraz was a restricted use pesticide in 1985 because some studies showed it caused cancer in mice. But re-evaluation of the evidence has led to the current classification of amitraz as an unrestricted or general use pesticide. In veterinary medicine, the most common use of amitraz is in tick collars, which contain 9% amitraz as an active ingredient. A collar for a large size dog contains 2.4g of amitraz ([Hugnet et al., 1996](#)). Amitraz is available as a 19.9% topical solution for dogs. All tickicide dips for cattle and sheep contain 0.025% amitraz as the active ingredient. In France, tick collars contain 8–9% amitraz, and external lotions contain 5–12.5% amitraz. The amitraz-containing product Metaban, which is a liquid concentrate and labeled for veterinary use, is commonly used for demodectic mange (*Demodex canis*) in dogs ([Farmer and Seawright, 1980](#)). Amitraz is also used to control ectoparasites on cattle, sheep, goats and pigs. Amitraz is not recommended for cats and horses ([Auer et al., 1984](#); [Gunaratnam et al., 1993](#)). There are several reports that have described amitraz poisoning in animals ([Roberts and Argenzio, 1979](#); [Turnbull, 1983](#); [Auer et al., 1984](#); [Hsu et al., 1984](#); [Grossman et al., 1993](#); [Hugnet et al., 1996](#); [Andrade et al., 2004](#)). With dogs, poisoning is most often associated with accidental ingestion of the collar, resulting in severe toxicity and sometimes fatal poisoning ([Grossman et al., 1993](#); [Hugnet et al.,](#)

FIGURE 49.1 Chemical structure of amitraz.

1996). Amitraz should not be used in diabetic animals as it adversely affects the levels of glucose and insulin (Hsu and Schaffer, 1988).

## PHARMACOKINETICS/ TOXICOKINETICS

Amitraz is a highly lipid soluble compound that is rapidly absorbed following oral ingestion or dermal application, thus making exposure potentially dangerous for animals as well as humans. In the stomach, amitraz can be metabolized to as many as six metabolites and some of them are potentially toxic. Dogs receiving amitraz (100mg/kg, PO) in a gelatin capsule revealed the pharmacokinetic parameters as follows: area under the curve ( $AUC_{0-48h} = 265.3 \pm 12.3 \text{ mg/h/ml}$ ), elimination  $t_{1/2}$  ( $23.4 \pm 2.3 \text{ h}$ ), time to reach peak plasma concentration ( $t_{max} = 5.0 \pm 0.7 \text{ h}$ ), and mean peak plasma concentration ( $C_{max} = 20.7 \pm 2.3 \text{ mg/L}$ ) (Hugnet *et al.*, 1996). From these data it is clear that amitraz has a long elimination half-life and a significant amount is absorbed, which is accountable for most of the observed signs. There is a strong association between plasma amitraz concentrations and clinical manifestations in dogs (Hugnet *et al.*, 1996). Recently, Marafon *et al.* (2010) reported similar findings in cats experimentally intoxicated with 0.4% amitraz bath dip, which was eight times greater than the recommended concentration. Hugnet *et al.* (1996) observed that clinical signs of toxicosis usually appeared around 1h after ingestion, with plasma concentration around 5mg/L, and signs lasted until the concentration of amitraz decreased. This information can be used to monitor accidental ingestion of amitraz by dogs. In ponies and sheep, amitraz has a brief half-life after intravenous (IV) administration because it is hydrolyzed in the blood by formaminidases (Pass and Mogg, 1995).

The two major metabolites of amitraz are 2,4-dimethyl-formanilide and N-(2,4-dimethylphenyl)-N'-methylformamidine. The former metabolite is a relatively weak methemoglobin-former in dogs and man. These metabolites are further catabolized to 2,4-dimethylaniline and ultimately to 4-amino-3-methylbenzoic acid, which is the principal metabolite found in the urine and liver (Aronson *et al.*, 1988; Jones, 1990).

In essence, amitraz and its metabolites are excreted primarily in the urine and feces.

## MECHANISM OF ACTION

Amitraz kills mites, ticks and other parasites by interfering with their nervous system. The tick's sharp barbed mouth parts become paralyzed and cannot pierce the skin, thereby inhibiting the tick from feeding on dogs. Attached ticks will then detach.

Amitraz in higher doses has been shown to produce toxicity in several animal species by stimulating  $\alpha_2$ -adrenergic receptors ( $\alpha_2$ -AR) resulting in impairment of consciousness, respiratory depression, convulsions, bradycardia, hypotension, hypothermia and hyperglycemia. In early studies, amitraz produced effects similar to that produced by a pure  $\alpha_2$ -AR agonist drug such as clonidine (Costa *et al.*, 1988; Jorens *et al.*, 1997). In a recent experimental study, Marafon *et al.* (2010) observed significant declines in heart rate and respiration rate of cats intoxicated with amitraz. Electrocardiography (ECG) on an amitraz-poisoned English bulldog revealed prolonged QT intervals (Malmasi and Ghaffari, 2010). Amitraz acts centrally to influence blood pressure and heart rate by  $\alpha_2$ -AR agonism which causes a reduction in peripheral sympathetic tone (Kobinger, 1978; Cullen and Reynoldson, 1990). In the peripheral vasculature, both  $\alpha_1$  and  $\alpha_2$ -ARs are involved in contributing to the vasoconstrictor action of amitraz which results in hypotension. It is suggested that the central  $\alpha_2$ -AR agonist activity of amitraz is responsible for CNS depression (Cullen and Reynoldson, 1990).

In addition to being an  $\alpha_2$ -AR agonist, amitraz is a potent inhibitor of the enzyme monoamine oxidase (MAO), which is responsible for degrading the neurotransmitters norepinephrine and serotonin, resulting in behavioral and neurotoxic effects (Aziz and Knowles, 1973; Moser and Macphail, 1988). Amitraz is also known to cause inhibition of prostaglandins (Yim *et al.*, 1978).

## TOXICITY

### Acute toxicity

Acute toxicity data of amitraz is available for laboratory animals. Oral  $LD_{50}$  is 650mg/kg in rats and 1600mg/kg in mice. Values of dermal  $LD_{50}$  in rabbits and rats are >200mg/kg and 1600mg/kg, respectively. Oral  $LD_{50}$  values of amitraz for dog, pig, guinea pig and baboons are reported to be 100, 100, 400 and 100mg/kg, respectively. The inhalation  $LC_{50}$  (6h) of amitraz for rats is 65mg/L

of air. The oral LD<sub>50</sub> in birds (bobwhite) is estimated at 788mg/kg, and dietary LD<sub>50</sub> in mallard is 7000mg/kg and in Japanese quail is 1800mg/kg. LC<sub>50</sub> is 0.74ppm in rainbow trout, 0.5ppm in bluegill and 3.2–4.2ppm in harlequin fish. The EPA classifies amitraz as a Class III slightly toxic pesticide.

Signs of acute amitraz poisoning in male and female rats treated with 440mg/kg and 365mg/kg, respectively, include coolness to touch, reduced spontaneous activity, increased episodes of activity, such as aggression in response to handling, and signs of debilitation (Hayes and Laws, 1991). Due to its widespread use, acute amitraz poisoning is often encountered in dogs and cats. Poisoning may occur by oral, inhalation or dermal exposure, but poisoning is most often via the oral route. Onset of clinical signs is noted within 30min to 2h after ingestion. Clinical signs of poisoning include GI disturbance, nausea, vomiting, diarrhea, staggering, disorientation, CNS and respiratory depression, bradycardia, hypotension and hypothermia. Biochemical changes include hyperglycemia and elevation of liver enzyme (transaminases) activity. In dogs, following a topical application, amitraz has been shown to increase plasma glucose and decrease insulin release when dogs were dipped at twice the recommended concentration (Hsu and Schaffer, 1988). When amitraz is formulated in xylene and propylene oxide, signs such as depression, ataxia, stupor and coma are likely attributed to the xylene and propylene oxide (Jones, 1990). Generally, signs and symptoms of amitraz poisoning subside within 24–48h, while in some cases it may take 7–10 days.

In dogs and cats, common side effects of the pesticide include anorexia, sedation and a dry skin and hair coat. Serious side effects include low blood pressure, hypothermia, hyperglycemia, mydriasis, bradycardia, slow intestinal rate, incoordination, ataxia, vasoconstriction, vomiting, diarrhea, seizures and in rare instances death. Animals exposed to amitraz may show signs of CNS stimulation or CNS depression, depending on the dose level and to some extent the species involved. Generally, at low doses CNS stimulation may occur, as manifested by hyperactivity to external stimuli such as handling and considerably increased food consumption (Pfister and Yim, 1977). High doses of amitraz have a CNS depressive effect with reduced spontaneous activity, bradycardia, respiratory depression and hypothermia. Oglesby *et al.* (2006) observed renal cortical necrosis and hemorrhage in a dog, which died from acute renal failure following ingestion of an amitraz-formulated dip. Untreated dogs and cats usually go into a coma and die from respiratory failure. Surviving animals show complete recovery from all signs and symptoms in about 7–10 days, even when exposed to higher doses (Bonsall and Turnbull, 1983).

Evidence from animal studies suggests that amitraz is a neurotoxicant (Moser and Macphail, 1988). Amitraz has been shown to produce many behavioral and physiological changes in rats. Amitraz at a dose greater than 100mg/kg caused inhibition of monoamine oxidase (MOA) within 2h of dosing and lasted up to 7 days. Amitraz appears to be more selective for type B-MAO when given *in vivo*, although MAO-A was also inhibited at doses  $\geq 300$ mg/kg. However, no selectivity was indicated by the IC<sub>50</sub> values determined *in vitro* (IC<sub>50</sub> = 31 and 28 $\mu$ M for MAO-A and MAO-B, respectively). Findings revealed that the MAO inhibition is probably not due to amitraz-induced alterations in motor activity. Amitraz produced only negligible inhibition of acetylcholinesterase at very high doses. In a dose-dependent manner, amitraz produced depressed arousal and rearing activity, hypothermia, body weight loss; and autonomic changes including ptosis, mydriasis, chromodacryorrhea resulting in facial crustiness, loss of the pupil reflex and decreased defecation in rats (Moser, 1991).

Horses poisoned by amitraz may show clinical signs of tranquilization, depression, ataxia, muscular incoordination and impaction colic that can last up to a week, followed by mild dehydration and acidosis.

## Chronic toxicity

In chronic 2-year feeding trials, rats receiving 50mg/kg/day in their diet or dogs receiving 0.25mg/kg/day of amitraz did not show any ill effects. Dogs given 1mg/kg/day exhibited signs of slight CNS depression and hypothermia, and blood analysis revealed significant hyperglycemia.

Studies suggest that amitraz exerts endocrine disrupting activity and reproductive and developmental toxicity. Male and female rats receiving amitraz at 200mg/kg/day for 10 weeks showed decreased fertility. Female mice treated with amitraz orally (50mg/kg/day) for 5 days and then mated showed a slight increase in loss of fetuses and a decrease in the number of living offspring. When male mice were given the same dose for the same duration and then mated, the resulting embryos were significantly less likely to grow in the mother's uterus. Rabbits who received 25mg/kg/day of amitraz from days 6 to 18 of pregnancy had fewer and smaller litters (Meister, 1994).

Being an  $\alpha_2$ -AR agonist, amitraz is reported to adversely affect the mammalian reproductive system by binding to presynaptic  $\alpha_2$ -AR in the hypothalamus, thus inhibiting noradrenalin release and decreasing gonadotropin-releasing hormone secretion (Altobelli *et al.*, 2001). In addition, several *in vivo* and *in vitro* studies have demonstrated that amitraz is a reproductive toxicant (Goldman and Cooper, 1993; Young *et al.*, 2005).

Amitraz also has the potential for teratogenic activity. In rats treated with 12 mg/kg/day of amitraz from day 8 to 20 of pregnancy, the offspring were heavier but had less bone development than the offspring of untreated rats (Hayes and Laws, 1991). In a recent investigation, Kim *et al.* (2007) showed that amitraz administered during the entire pregnancy period in rats is embryotoxic and teratogenic at the maternally toxic dose (i.e., 30 mg/kg/day) and is minimally embryotoxic at a minimal maternally toxic dose (i.e., 10 mg/kg/day). Amitraz and its metabolite 2,4-dimethylaniline have also been shown to induce teratogenic effects in frog embryos (Osano *et al.*, 2002).

Studies in laboratory animals have shown that amitraz has no potential for mutagenic activity and does not cause damage to DNA (Hayes and Laws, 1991). Amitraz can cause tumors in female mice but not in male mice or male or female rats. EPA has established the teratogenic no observed effect level (NOEL) in rats at 12 mg/kg/day (Walker and Keith, 1992). The teratogenic NOEL in rabbits is 25 mg/kg/day.

## Diagnosis

Most of the time, poisoning in animals (especially dogs and cats) with amitraz is acute. Diagnosis is based on history of exposure, presence of the collar's pieces in the stomach on X-ray, clinical signs of toxicity associated with stimulation of  $\alpha_2$ -AR, and residue analysis. Due to a long half-life, residue of amitraz and its major metabolites can be detected in the plasma of a poisoned animal using GC coupled with a nitrogen-phosphorus detector or a thermionic-specific detector (Ameno *et al.*, 1991; Marafon *et al.*, 2010), or HPTLC coupled with a UV detector (Hugnet *et al.*, 1996).

## TREATMENT

In most cases, symptomatic and supportive therapies are of great value. Remove the tick collar or any other source of amitraz from pets. IV fluids are recommended. In the case of dermal exposure, bathing is helpful. For oral ingestion, induction of vomiting and gastric lavage is recommended. Administration of activated charcoal with a saline cathartic is also beneficial. Animals should be kept in the warm, as amitraz causes hypothermia. Continuous monitoring of cardiovascular, respiratory and central nervous systems, and of glucose and insulin levels is advised.

Studies from animals suggest that the  $\alpha_2$ -AR antagonists (yohimbine and atipamezole) can reverse amitraz-induced toxicity. In dogs, yohimbine has been found to

be very effective. Bradycardia and hypotension respond to yohimbine administration (Hsu and Schaffer, 1988). Dogs severely poisoned with amitraz have been successfully treated with low doses (50  $\mu$ g/kg, IM) of the potent  $\alpha_2$ -AR antagonist atipamezole (Hugnet *et al.*, 1996). Doses of atipamezole can be repeated after 3 to 4 h, if necessary. Atipamezole can control all the clinical effects of amitraz within 20 min. With good care and aggressive treatment, even severe cases can be recovered.

## CONCLUSIONS

Amitraz is widely used as an insecticide and acaricide in veterinary medicine. Dogs and cats are intoxicated due to accidental ingestion of amitraz-containing tick collars and other products. Major toxic signs are associated with  $\alpha_2$ -adrenergic receptor ( $\alpha_2$ -AR) agonism, such as CNS depression, hypotension, bradycardia, and hypothermia. Increased blood glucose and decreased insulin secretion are characteristics of amitraz poisoning and are also due to  $\alpha_2$ -AR stimulation. With timely administration of an  $\alpha_2$ -AR blocker (yohimbine or atipamezole), and conventional therapeutic measures, even seriously intoxicated cases can recover.

## ACKNOWLEDGMENTS

I would like to thank Mrs. Robin B. Doss and Ms. Michelle A. Lasher for their assistance in the preparation of this chapter.

# Fipronil

Arturo Anadon and Ramesh C. Gupta

## INTRODUCTION

Fipronil is a member of a new class of insecticides called phenylpyrazoles. Chemically, it is a (5-amino-1-[2,6-dichloro-4-(trifluoromethyl)phenyl]-4-[(trifluoromethyl)sulfinyl]-1*H*-pyrazole). The chemical structure of fipronil is shown in Figure 50.1. Fipronil is an active ingredient of one of the popular ectoparasiticides products Frontline™. There are currently two forms of Frontline preparation commercially available (the spray and the spot-on topical application) for dogs and cats. The product is meant to kill fleas and all stages of brown dog ticks, American dog ticks, lone star ticks, which may carry Lyme disease and mites (Cutler, 1998; Hutchinson *et al.*, 1998; Anonymous, 2000). Fipronil is used in combination with methoprene (9.8% fipronil/11.8% methoprene for cats; 9.8% fipronil/8.8% methoprene for dogs) for additional control of immature flea stages. Fipronil is also formulated as insect bait for roaches, ants and termites; sprays for pets; and as a granular turf product to control mole crickets. Presently, fipronil is widely used in agriculture for soil treatment and seed coating.

FIGURE 50.1 Chemical structure of fipronil.

Currently, fipronil-based products with various trade names (Chipco®, Choice, ICON 6.2FS™, and Over n' Out™, TeckPac, Frontline) have gained popularity worldwide for pest management, including residential insect control, rice and cotton production, and turf-grass management. EPA has determined fipronil to be safe for use on dogs and cats, with no harm to humans who handle these animals. Poisoning cases from accidental or misuse of fipronil may occur in animals. This chapter describes the toxicity of fipronil in various species of animals, birds and fish.

## BACKGROUND

Fipronil was first discovered by Rhone-Poulenc Agro in 1987 and is used worldwide in agriculture. It represents the second generation of insecticides that acts through a different mechanism compared to other conventional insecticides. It is poorly soluble in water, delivered in very small amounts and does not leach into the groundwater. In 1996, it was registered as a pesticide in the U.S. (Bobe *et al.*, 1998). It can be formulated as roach or ant baits, flea and tick sprays for pets, and in granular turf products to control mole crickets (Kidd and James, 1991; EPA, 1996). In addition, fipronil is used for soil treatment and on crops to protect from insects. It is currently used in over 50 countries and has good adulticide activity against fleas and ticks. It has significant residual activity and for small animal use is available as a spray or spot-on product. Sunlight, immersion in water and bathing do not significantly impact the performance of

this compound and it kills adult fleas within 24 hours (Kunkle, 1997). Fipronil has also been used to treat some mite infections.

Most of the time poisoning cases of fipronil occur in dogs and cats due to accidental ingestion or licking the product Frontline. Frontline preparation for dogs contains 132mg fipronil in a volume of 1.34ml tube that is meant for a topical application. In humans, poisoning is mainly due to accident or suicidal attempt. In a recent report, the Paris Poison Center, France, recorded 81 human cases of fipronil exposure from 1994 to 1999. Out of these 81 cases, 57 involved veterinary ectoparasitocides and seven used domestic insecticide preparations (Gasmi *et al.*, 2001).

## PHARMACOKINETICS/ TOXICOKINETICS

Fipronil in Frontline preparation (132 mg in a 1.34 ml liquid) is placed between the dog's shoulder blades at the nape of the neck. After application, fipronil spreads and sequesters in the lipids of the skin and hair follicles, and continues to be released onto the skin and coat, resulting in long-lasting residual activity against fleas and ticks. Residue of fipronil lasts on a dog's hair coat for about a month. The maximum concentration of fipronil on the canine hair coat is found 24h after a single application of Frontline top spot (Jennings *et al.*, 2002). With a descending concentration trend fipronil residue can be detected on dog's hair coat for a period of 30 days (Figure 50.2). Although fipronil binds to the lipids of the skin cells and

**FIGURE 50.2** Transferable residue of fipronil from the dog coat after a single application of Frontline spot-on.

hair follicles, the transferable residue can be detected up to a month after application. Studies have revealed that in rats, fipronil is excreted mainly in the feces (45–75%) and little in the urine (5–25%). In rats, once absorbed, fipronil is rapidly metabolized, and then the biotransformation products are widely distributed in tissues. Significant amounts of metabolites can persist in the tissues, particularly in fat and fatty tissues, for one week after treatment. The metabolite concentrations in fat and other tissues are greater with repeated low doses or a single high dose than with a single low dose. The long half-life (150–245 h in some cases) of fipronil in blood may reflect slow release of metabolites from fat. The compounds identified in feces and urine are the parent compound and the sulfone, the amide derived from the nitrile group and a cleavage product of the sulfone and its derivatives formed by further metabolism. The sulfone is the major metabolite in fat and tissues.

In another pharmacokinetics study the rats received either a single oral dose of labeled compound ( $^{14}\text{C}$ -fipronil-desulfinyl) at 1 or 10 mg/kg body weight or daily oral doses of unlabeled compound at 1 mg/kg body weight/day for 14 days, followed by a single oral labeled dose. In animals of both sex, elimination of the radiolabeled fipronil was much greater in the feces (46–70% of the dose) than in the urine with all dosing regimens. Appreciable metabolic products were found in the tissues 1 week after treatment, the highest concentrations being present in the fat and fatty tissues. The long half-life in blood was 183–195 h and fat:plasma ratio of the radiolabel compound was increased. Numerous metabolites or conjugates of fipronil desulfinyl were present in the urine and feces. Only unchanged fipronil desulfinyl was identified in the liver, fat, skin and body. There was no appreciable difference between male and female rats in the absorption, distribution, metabolism or excretion of fipronil after oral administration. Fipronil is degraded by sunlight to produce a variety of metabolites, one of which is fipronil desulfinyl. This metabolite is extremely stable, bioaccumulates in the fatty tissues and is more toxic than the parent compound in insects (EPA, 1998). Information on other metabolites of fipronil in the living system and nonliving system can be found elsewhere (Feung and Yenne, 1997; Aajoud *et al.*, 2003). This photoproduct exerts high neurotoxicity by blocking the GABA-regulated chloride channels. Fipronil has a greater specificity for the GABA receptor found in insects than mammalian GABA receptors. Fortunately, this metabolite is not formed in mammals. However, it does have high affinity towards the insect's GABA system, thereby contributing to fipronil's selective toxicity toward insects.

It is known that fipronil is an effective inducer of CYP isoforms in human hepatocytes. Fipronil can inhibit testosterone metabolism by CYP3A4. Since fipronil is a

hepatotoxicant at doses somewhat above those required for induction, the decrease may represent one of the initial toxic effects, with CYP3A4 induction being more sensitive than CYP1A1 induction. Fipronil has the potential to interact with a wide range of xenobiotics or endogenous chemicals that are CYP3A4 substrates. In the case of possible metabolic interactions based on the induction or inhibition of xenobiotic metabolizing enzymes, the concentrations of fipronil at the active site(s) become crucial.

## MECHANISM OF ACTION

In mammalian systems, the mechanism of fipronil is quite different from other classes of insecticides, and it is better understood in insects than in mammals. Fipronil sulfone is a major metabolite of fipronil in mammals and insects. In invertebrates (insects), fipronil or its metabolite non-competitively inhibits  $\gamma$ -aminobutyric acid (GABA)-induced ion influx by targeting the GABA-regulated chloride channels (Cole *et al.*, 1993). Consequently, fipronil binding blocks the inhibitory action of GABA, leading to neural hyperexcitation, and at sufficient concentrations, paralysis and death (Bobe *et al.*, 1998). Fipronil exhibits >500-fold selective toxicity to insects over mammals, primarily because of affinity differences in receptor binding between insect and mammalian receptors (Cole *et al.*, 1993; Grant *et al.*, 1998; Hainzl *et al.*, 1998; Kamijima and Casida, 2000; Ratra *et al.*, 2001; Zhao *et al.*, 2005; Narahashi *et al.*, 2010). In essence, fipronil binds more tightly to GABA<sub>A</sub> receptors in insects than in mammals. It is important to note that since fipronil sulfone is rapidly formed *in vivo*, the toxicological effects are likely due to the sulfone metabolite (Zhao *et al.*, 2005).

The toxicity of fipronil desulfinyl is qualitatively similar to that of fipronil, but the dose–effect curve for neurotoxic effects appears to be steeper for fipronil desulfinyl than for fipronil. Also, fipronil desulfinyl appears to have a much greater tendency than fipronil to bind to sites in the chloride ion channel of the rat brain GABA receptor. This finding appears to be consistent with the greater toxicity, relative to fipronil, of fipronil desulfinyl in the CNS of mammals.

Different studies have shown that fipronil reveals thyroid disrupting properties in rats. Mechanistic investigations conducted with fipronil in rats suggest that it does not interfere with the incorporation of iodine into thyroxine (T<sub>4</sub>), but it interferes with the biliary clearance of this hormone. This may trigger an increase in the concentration of thyroid-stimulating hormone by interference with the feedback mechanism and decreased thyroxine concentrations.

## TOXICITY

Fipronil produces toxicity in insects and mammals by the same mechanism; however, due to selective action, the toxicity is much more severe in insects than in mammals. Fipronil and other phenylpyrazole compounds exert neurotoxicity by blocking transmission of signals by inhibitory neurotransmitter  $\gamma$ -aminobutyric acid (GABA). These compounds bind within the chloride channels and consequently inhibits the flux of chloride ions into the nerve cell, resulting in hyperexcitation.

There are numerous reports regarding the effects of fipronil in small animals, birds and fish (<http://www.cdpr.ca.gov/docs/empmpubs/fatememo/fipronil.pdf>).

### Laboratory animals

Adequate acute toxicity data are available from small animals. Fipronil is moderately hazardous to rats (LD<sub>50</sub> = 97mg/kg body weight) and mice (LD<sub>50</sub> = 95mg/kg body weight). In rats, signs of toxicity and death were delayed for up to 4 days after a single dose or repeated oral doses of 75mg/kg body weight per day for up to 5 days.

Fipronil has moderate inhalation toxicity with an acute LC<sub>50</sub> of 0.682mg/L in rats (EPA, 1996).

It is nontoxic to slightly toxic via the dermal route, with a reported dermal LD<sub>50</sub> of greater than 2000mg/kg in rats (EPA, 1996). In rabbits, fipronil was found to be moderately hazardous after dermal application (LD<sub>50</sub> = 354mg/kg body weight; WHO, 1998–1999). In general, dermal absorption of fipronil is less than 1% after 24 h and therefore dermal toxicity is considered low. In a dermal toxicity study, fipronil was applied (0.5% in carboxymethylcellulose) to the intact skin of rabbits for 6 h per day, 5 days a week, for 3 weeks at doses of 0, 0.5, 1, 5 or 10mg/kg body weight per day. No dermal irritation was observed. At 10mg/kg body weight per day, body weight gains and food consumption were reduced in animals of either sex. Some animals showed hyperactivity. The NOAEL was identified to be 5mg/kg body weight per day. Primary dermal irritation in rabbits was examined in two studies. Fipronil was slightly irritating when moistened with corn oil before application, but was not irritating when moistened with water. Fipronil was slightly irritating in two studies of primary ocular irritation in rabbits. It did not sensitize the skin of guinea pigs when tested by the Buehler method but was a weak sensitizer in guinea pigs tested by the Magnusson-Kligman method (WHO, 1998–1999). This product was reported to be contraindicated in rabbits because deaths occurred when spray formulation of fipronil was used. Extra-label use in rabbits could

produce anorexia, lethargy, convulsions and death. In rabbits, fipronil produces serious adverse reactions, suggesting that this species is unusually sensitive to fipronil. Young rabbits are especially more sensitive than adults. Frontline has been considered to be improper for rabbits.

One reproductive toxicity study was performed in rabbits (WHO, 1998–1999). Rabbits treated with fipronil by gavage at doses of 0, 0.1, 0.2, 0.5 or 1 mg/kg body weight per day during gestation days 6–19 showed no developmental toxicity, but there were some signs of maternal toxicity (decreased body weight gain, decreased food consumption and reduced efficiency of food use at all doses). The NOAEL for developmental toxicity was identified to be 1 mg/kg body weight per day. Fipronil has also been found to be a developmental neurotoxicant in the PC12 cells and zebrafish models (Stehr *et al.*, 2006; Lassiter *et al.*, 2009).

### Dogs and cats

Several subacute and chronic toxicity studies of fipronil have been performed in dogs (WHO, 1998–1999). In a subacute toxicity study, fipronil was administered in gelatin capsules to dogs for 13 weeks at doses of 0, 0.5, 2 or 10 mg/kg body weight per day. Inappetence and decreased body weight gain and food consumption were noted in females at 2 and 10 mg/kg body weight per day. The NOAEL was reported to be 0.5 mg/kg body weight per day.

In a chronic study, fipronil was administered to dogs in gelatin capsules for 1 year at doses of 0, 0.2, 2 or 5 mg/kg body weight per day. At 2 mg/kg body weight per day and above, there were clinical signs of neurotoxicity (convulsions, twitching, tremors, ataxia, unsteady gait, rigidity of limbs, nervous behavior, hyper- or hypoactivity, vocalization, nodding, aggression, resistance to dosing, inappetence and abnormal neurological responses) in animals of both sex. One animal at 2 mg/kg body weight per day was killed because of poor condition related to treatment. The NOAEL was identified to be 0.2 mg/kg body weight per day. In another study, fipronil was administered in the diet at doses of 0, 0.075, 0.3, 1 or 3 mg/kg body weight per day for 1 year. At 1 mg/kg body weight per day, clinical signs of neurotoxicity (whole body twitching and extensor rigidity of limbs) were noted in females. There were no effects on triiodothyronine or thyroxine levels. The NOAEL was identified to be 0.3 mg/kg body weight per day.

A neurotoxicity study was performed in female dogs (WHO, 1998–1999). In this study, dogs received fipronil in capsules at doses of 0 (one animal) or 20 mg/kg body weight per day (four animals) until the appearance of neurotoxic signs in each animal, after which they were allowed to recover for 28 days. Severe neurotoxic signs

were observed at a dose of 20 mg/kg body weight per day during the treatment phase. Most animals appeared to recover, although one had exaggerated reflex responses and was excitable at the end of the recovery period.

Poisoning cases of fipronil occur in dogs and cats due to accidental ingestion/licking of Frontline product. There is some indication that dogs are more severely affected than cats. Application of Frontline spot-on to dogs and cats can cause skin irritation and/or hair loss at the site of application. Dermal hypersensitivity reactions may also occur. Common clinical signs of fipronil toxicosis are of CNS hyperexcitability, including tremors, convulsions, seizures and death (Grant *et al.*, 1998; Hainzl *et al.*, 1998; Kamijima and Casida, 2000).

### Birds and fish

On an acute and subchronic level fipronil is practically nontoxic to slightly toxic in waterfowl with an acute oral LC<sub>50</sub> of >2000 mg/kg and a 5-day dietary LC<sub>50</sub> of >5000 mg/kg in mallard ducks. The oral LC<sub>50</sub> for bobwhite quail is 11.3 mg/kg, and the LC<sub>50</sub> for 5-day dietary is 49 mg/kg (EPA, 1996). The sulfone metabolite is more toxic than the parent compound to certain bird species. This metabolite has shown a very high toxicity in game birds and moderate toxicity in waterfowl (EPA, 1996; Bobe *et al.*, 1997). Fipronil is highly toxic to rainbow trout and very highly toxic to bluegill sunfish with an LC<sub>50</sub> of 0.246 mg/L and 0.083 mg/L, respectively. WHO classifies fipronil as a Class II moderately hazardous pesticide.

## DIAGNOSIS

Diagnosis of a fipronil poisoning can be based on circumstantial evidence, clinical manifestations and chemical confirmation. Fipronil residue can be detected in the blood, tissue or hair, using GC/MS. Transferable residue of fipronil can be detected on a dog hair coat up to 4 weeks after a single spot-on application (Figure 50.2).

## TREATMENT

There is no specific treatment for the toxicity of fipronil, and therefore treatment relies upon symptomatic and supportive measures. If a dog or cat shows adverse reaction to topical application of Frontline, decontamination by washing at the site of application is advisable. The ingestion of any fipronil topical veterinary product

should be treated by the ingestion of water or milk. The most recommended methods of internal decontamination include gastric lavage, and administration of activated charcoal (1–4 g/kg) and cathartic agent within 3–4 hours.

If hypersensitivity skin reactions occur after application of any topical product, the animals should be submitted for a bath with a non-insecticidal shampoo and symptomatic treatment (e.g., antihistamines, hydrocortisone or antibiotics).

## CONCLUSIONS

Fipronil elicits neurotoxicity in mammals by inhibition of GABA<sub>A</sub>-gated chloride channels, producing hyperexcitability of CNS. Overdosage due to accidental ingestion often leads to serious toxicosis in dogs and cats. There is no specific antidote for the toxicity of fipronil. The manufacturer warns that the product may be harmful to debilitated, aged, pregnant or nursing animals and also stated that fipronil must not be used in kittens less than 12 weeks of age and on puppies less than 10 weeks old.

# Macrocyclic lactone endectocides

Sharon M. Gwaltney-Brant, Camille DeClementi and Ramesh C. Gupta

## INTRODUCTION

Macrocyclic lactones (MLs) consist of a number of compounds (doramectin, eprinomectin, ivermectin, milbemycin, moxidectin and selamectin) that are commonly used as insecticides, acaricides and nematicides in various animal species. Chemical structures of these MLs are shown in Figures 51.1–51.6. Ivermectin, a semi-synthetic ML, was the first to be obtained from *Streptomyces avermitilis*. Ivermectin/abamectin is a mixture of two homologs, i.e., ivermectin B<sub>1a</sub> and ivermectin B<sub>1b</sub> (Figure 51.1). It was introduced to the market in 1981 as a potent antiparasitic animal health drug. It has been found to be effective against virtually all external and internal parasites thus far tested, with the exception of trematodes and cestodes. The drug is approved at a very low dosage for the control of parasites in many animal species (cattle, sheep, swine, horse, cat and dog), but not approved in lactating cows, sheep and goats. In agriculture, ivermectin is used for its miticidal, insecticidal and acaricidal activities.

Although ivermectin poisoning has been reported in many animal species due to inadvertent or misuse of the product (Godber *et al.*, 1995; Haldrick *et al.*, 1995), a major concern of ivermectin toxicosis is in individuals of certain dog breeds, such as collies (Paul *et al.*, 1987), which are very sensitive to this drug due to a genetic defect in the blood–brain barrier (BBB). To date, over 11 dog breeds (Houston, *et al.*, 1987; Geyer *et al.*, 2007; Mosher and Court, 2010), Murray Grey cattle (Seaman *et al.*, 1987) and young animals have been reported to be more sensitive to ivermectin toxicosis.

Selamectin, a novel semi-synthetic avermectin, is marketed as Revolution™ (Pfizer). Revolution™ is a topical antiparasitic preparation recommended for use

in dogs and cats 6 weeks of age and older. Selamectin is used to kill fleas (*Ctenocephalides felis*) and ear mites (*Otodectes cynotis*) in dogs and cats. It is also indicated for the treatment and control of sarcoptic mange (*Sarcoptes scabiei*) and for the control of tick (*Dermacentor variabilis*) infestations in puppies, as well as for the treatment of hookworm (*Ancylostoma tubaeforme*) and roundworm (*Toxocara cati*) infections in kittens. Selamectin is also used to prevent heartworm disease caused by *Dirofilaria immitis*. Most recently, Jacsó *et al.* (2010) reported the efficacy of selamectin in the treatment of subcutaneous dirofilariosis in dogs caused by *Dirofilaria repens*. In addition to ivermectin and selamectin, there are many other macrocyclic lactones which pose a serious threat to animal health following accidental or overdose exposure. This chapter describes the toxicity of macrocyclic lactone endectocides in animals.

## BACKGROUND

Currently, there are many macrocyclic lactones (MLs) available in the market for their wide applications as insecticides, nematicides and acaricides. But ivermectin and its derivatives are most popular because of their efficacy and wide margin of safety. Ivermectin/abamectin is a mixture of two homologs, i.e., not less than 80% of 22,23-dihydroavermectin B<sub>1a</sub> and not more than 20% of 22,23-dihydroavermectin B<sub>1b</sub>. B<sub>1a</sub> and B<sub>1b</sub> components differ from each other by a single methylene group, have very similar biological and toxicological properties, and can, for all practical purposes, be considered equipotent (Campbell, 1989). The mixture is sold commercially

FIGURE 51.1 Chemical structure of abamectin (right, ivermectin B<sub>1a</sub>; and left, ivermectin B<sub>1b</sub>).

FIGURE 51.4 Chemical structure of milbemycin.

FIGURE 51.5 Chemical structure of moxidectin.

as abamectin. It is a drug of choice because of its broad spectrum nematicidal, insecticidal and acaricidal properties, and it has been approved for prophylactic use against heartworm (*Dirofilaria immitis*) infection in dogs.

Ivermectin is utilized at a very low dosage. It is effective against a wide range of helminths in sheep and cattle in a single oral or parenteral dose of 0.1 mg/kg body weight (Egerton *et al.*, 1979). It is recommended in a variety of species, including dogs, cats, sheep, goats, swine, feedlot beef cattle, horses and reindeer. The tolerances for beef cattle, reindeer, swine and sheep are 15, 15, 20 and 30 ppb ivermectin B<sub>1a</sub>, respectively (CFR, 1990). Ivermectin is not approved for lactating animals.

In the case of beagles the dose required for prevention of heartworm disease is 6 µg ivermectin/kg body weight, while the oral LD<sub>50</sub> of this drug in the same breed is 80,000 µg/kg body weight (Pullium *et al.*, 1985). However, certain dogs exhibit signs of toxicosis when given ivermectin at oral doses in the range of 100–2500 µg/kg body weight (Easby, 1984; Houston, 1987). Although this dosage level exceeds the approved heartworm preventive

FIGURE 51.6 Chemical structure of selamectin.

dose for dogs, it has been administered inadvertently by the improper use of formulations which were meant for cattle, sheep, horses and swine. Additionally, oral dosages of ivermectin of 200–600 µg/kg are frequently used by veterinarians to manage Sarcptic and Demodectic mange in dogs. Poisoning in several animal species has been reported due to overdosage of ivermectin. Young animals in general are more sensitive than adults because their immature BBB are more permeable to ivermectin (Sanford *et al.*, 1988).

Topical application of Revolution™ (6 mg selamectin/kg body weight) has been shown to have a broad range of efficacy against many external and internal parasites of dogs and cats (Jacobs, 2000; Dryden *et al.*, 2001). Following topical administration of Revolution™ to a single site on the skin, selamectin is absorbed by the animal, enters the bloodstream and the GI tract, and it is ingested by the external and internal parasites as they feed on the treated host. Selamectin has been shown to have a direct parasitocidal effect following ingestion (Bishop *et al.*, 2000; Pfizer, 2001). Selamectin has a wide margin of safety, but poisoning can occur due to overdosage or accidental exposure.

Other MLs are variously used as injectable, oral and topical products in livestock, including abamectin (Duotin®, injectable), doramectin (Dectomax®, injectable and pour-on), eprinomectin (Eprinex®, pour-on) and moxidectin (Cydectin®; oral, injectable and pour-on) in dosages ranging from 200 to 1000 µg/kg. Moxidectin is also utilized as heartworm preventives in dogs at dosages of 3 µg/kg orally and 17 µg/kg as subcutaneous sustained-release injection (ProHeart®6). Milbemycin (Interceptor®) is used as an oral heartworm preventive in dogs at dosages of 500 µg/kg and cats at dosages of 2000 µg/kg.

## PHARMACOKINETICS/ TOXICOKINETICS

The extended antiparasitic activity of MLs in mammals is due to the unique pharmacokinetic profile of this class of compounds. MLs tend to have prolonged tissue and plasma residence times due to their relatively slow absorption, wide tissue distribution, low rate of metabolism and slow rate of elimination (Lanusse *et al.*, 2009). Characteristics of MLs that influence these kinetic properties include strong adsorption to gastrointestinal particulate digesta, extensive and reversible plasma-tissue exchanges, relatively high degree of lipophilicity, extensive biliary and p-glycoprotein mediated intestinal secretion and extensive enterohepatic recycling. With most MLs, the pharmacokinetic properties are dose dependent and highly dependent upon the formulation of the individual compounds. For instance, when injected subcutaneously, ivermectin formulations that are oil-based have a slower absorption than those based in glycerol or propylene glycol (Gonzalez *et al.*, 2007).

In general, MLs are well absorbed following injection, oral or topical administration, although species differences in absorption and bioavailability have been noted for some MLs. For instance, the bioavailability of selamectin following topical administration was 4.4% in dogs and 74% in cats, while the oral bioavailability in dogs and cats was 62% and 109%, respectively (Sarasola *et al.*, 2002). Moxidectin absorption is enhanced by co-administration of lipid in most species, but not in dogs (Lallemant *et al.*, 2007). Additionally within species, sex-related differences in absorption or bioavailability have been reported, including increased absorption of ivermectin and doramectin in female bovines (Toutain *et al.*, 1997).

MLs distribute widely throughout the body and tend to have long tissue residence times, resulting in prolonged antiparasitic activity. The degree of body fat can play a major role in the distribution of MLs, which in turn controls the terminal half-life of the individual animal; for instance, the elimination half-life of moxidectin in dogs with a high body fat content is longer than the half-life in leaner dogs (Lallemant *et al.*, 2007). ML levels in tissues such as the gastrointestinal mucosa, lungs and skin may exceed that of plasma for days to weeks following administration (Lanusse *et al.*, 2009). Doramectin achieves high concentrations in pulmonary tissue of cattle, making it highly effective against the lungworm *Dictyocaulus viviparus*. Following topical administration, selamectin is absorbed into the bloodstream and excreted via the bile into the intestinal tract, where it is reabsorbed and selectively distributed to the sebaceous glands in the skin (Gupta *et al.*, 2005; Gupta, 2007). This unique multiphasic distribution accounts for the ability of selamectin to control hematogenous, gastrointestinal and integumentary parasites following topical administration.

Although they have widespread distribution to most body tissues, MLs are largely excluded from the mammalian brain through the action of the BBB's p-glycoprotein transport system (P-GP) (Figure 51.7). The P-GP is a 170kDa trans-membrane protein coded for by the ABCB1 (formerly MDR1) gene and is located primarily in the intestine, liver, kidney and brain (Mosher and Court, 2010). The function of P-GP is to limit the systemic and brain uptake of certain xenobiotics and enhance their elimination from the body (Shen and Zhang, 2010). Alterations in P-GP function can result in increased systemic xenobiotic levels and enhanced penetration of xenobiotics into the brain. MLs comprise one family of drugs that serve as substrates for P-GP, therefore animals with defects within the P-GP system may have increased absorption and decreased elimination of MLs, as well as an influx of MLs into the CNS, where ML-sensitive GABA-gated chloride channels reside. Such animals will be hypersensitive to the neurologic effects of MLs at levels well below those tolerated by animals with intact P-GP and will show signs of toxicosis at relatively low levels. Alteration of P-GP function may occur via genetically mediated abnormalities or drug-drug interactions. The administration of drugs that alter P-GP function can also increase the sensitivity of an individual to the neurologic effects of MLs. P-GP inhibiting drugs such as ketoconazole can increase absorption and decrease elimination of MLs, increasing the likelihood of neurotoxicosis (Hugnet *et al.*, 2007).

In dogs, a 4 base-pair deletion resulting in a frame-shift mutation in the ABCB1 gene has been identified within several breeds (Mosher and Court, 2010). Affected dogs possess truncated, non-functional P-GP and are extremely sensitive to the effects of xenobiotics that serve as substrates for P-GP (Mealey, 2004). First identified in collies, the ABCB1 defect has also been identified in over 11 breeds of dogs, as well as mixes of these breeds (Geyer *et al.*, 2007; Mosher and Court, 2010). Table 51.1 lists the breeds in which ABCB1 defects have been identified. Interestingly, although increased brain penetration of xenobiotics has been demonstrated in dogs with the ABCB1 mutation, pharmacokinetic studies have shown no significant differences in oral bioavailability between dogs with mutant ABCB1 and wild-type dogs (Mealey *et al.*, 2010). Affected dogs develop clinical effects of ML toxicosis at levels that do not cause clinical signs in dogs with normal P-GP. Recently, a novel insertion mutation in the ABCB1 gene was found to be associated with ivermectin sensitivity in a border collie that lacked the previously described deletion mutation (Han *et al.*, 2010), suggesting that more than one genotypic abnormality may result in a similar phenotypic expression.

Although MLs undergo some metabolism, the majority are excreted unchanged in the feces via the bile. This excretion into the intestine results in reabsorption and enterohepatic recycling of up to 20% of the total dose of ML administered (Lanusse *et al.*, 2009). The fact that

**FIGURE 51.7** Cartoon of normal p-glycoprotein function within the blood–brain barrier (BBB). P-glycoprotein is a transmembrane pump (gray trapezoids) located on the apical (blood-facing) side of endothelial cells that form the BBB. These endothelial cells are joined through tight junctions (T.J.) that prevent diffusion of substances between the cells. (1) P-glycoprotein substrates (diamonds) diffuse into and out of the endothelial cells through the lipid bilayer of the cell membrane. (2) Substrates within the cell or cell membrane are taken up by the p-glycoprotein molecule, an active process requiring ATP for energy. (3) Once taken up by the p-glycoprotein, substrates are ejected back into the bloodstream. Defects in p-glycoprotein structure and/or function can result in increased concentrations of substrates within the endothelial cell, and egress of substrates out the basal side of the cell into the brain.

parenterally administered ML ultimately ends up being secreted into the bile and thereby enters the intestinal tract to undergo some degree of enterohepatic recycling largely explains the efficacy of injected MLs against intestinal parasites. Up to 95% of an ML dose is excreted unchanged in the feces and the half-lives for the various MLs are in the range of days to weeks rather than hours. Half-lives for the various MLs vary widely depending on formulation, dose administered and species, as well as the relative amount of body fat (Lo *et al.*, 1985; Fink and Porras, 1989; Lallemand *et al.*, 2007).

There have been many ML pharmacokinetic/toxicokinetic studies conducted in dogs, cats, sheep, goats, cattle, horse and pigs (Tway *et al.*, 1981; Lo *et al.*, 1985; Prichard *et al.*, 1985; Alvinerie *et al.*, 1987, 1993; Marriner *et al.*, 1987; Bogan and McKeller, 1988; Toutain *et al.*, 1988, 1997; Fink and Porras, 1989; Scott and McKeller, 1991; Godber *et al.*, 1995; Sarasola *et al.*, 2002; Gupta *et al.*, 2005). It is evident from many of these studies that ivermectin and its derivatives are excreted in the milk.

## MECHANISM OF ACTION

The MLs exert their toxic actions through their high affinity for ligand-gated chloride channels, particularly those mediated through the neurotransmitters gamma-aminobutyric acid (GABA) and glutamate, with higher concentrations required for GABA-mediated effects than for glutamate-mediated actions (Lanusse *et al.*, 2009). Glutamate-gated channels are unique to invertebrates (Trailovic and Nedeljovic, 2010). Binding of MLs to glutamate-gated chloride channels causes increased conductance of chloride through the cell membrane, resulting in hyperpolarization and flaccid paralysis of invertebrate musculature, particularly in nematodes and arthropods (Lanusse *et al.*, 2009). In particular, paralysis

of pharyngeal pump musculature decreases the ingestion of nutrients while paralysis of somatic musculatures impedes the ability of the parasite to remain at its site of predilection in the host, resulting in death of the parasites. Additionally, effects on the GABA and glutamate-mediated activity of the musculature of the female reproductive system results in decreases in ovi-position (Fellowes *et al.*, 2000).

Glutamate-mediated chloride channels sensitive to MLs are found uniquely in nematodes and arthropods. Cestodes and trematodes lack ML binding sites, and are therefore unaffected by MLs. In mammals, ML-sensitive GABA-mediated chloride channels are restricted to the CNS, from which the MLs are largely excluded through the action of a p-glycoprotein efflux pump (see MLs and p-glycoprotein defective animals in previous section). When the p-glycoprotein transporter is overwhelmed (e.g., in overdose situations), defective (e.g., ABCB1 defect) or compromised (e.g., pharmacologically inhibited) entry of MLs into the mammalian CNS may lead to signs of toxicosis.

## TOXICITY

### Toxicity data

At the doses used as parasiticides in veterinary medicine, MLs have a fairly low level of toxicity to the majority of animal species with at least a ten-fold margin of safety for ruminants, horses, swine and dogs with normal P-GP (Lanusse *et al.*, 2009). For example, the dosage of ivermectin used to prevent heartworms and intestinal nematodes in dogs is 6 µg/kg body weight, which is over 30 times less than the dosage of 200 µg/kg that is often used in dogs to manage ectoparasites such as *Demodex* mites. Dogs with ABCB1 defects would not be expected to show clinical signs until levels of 80–100 µg/kg of ivermectin were administered, while dogs with normal P-GP can generally tolerate doses of 200 µg/kg/day (Merola *et al.*, 2009). Toxic and therapeutic dosages for some macrolides are listed in Table 51.2.

TABLE 51.2 Toxicity of various macrocyclic lactone endectocides

Agent	Species	Therapeutic dose (route)	NOAEL	Toxic dose (LOEL or MTD unless otherwise stated)	Comments/References

## Clinical effects

The clinical signs of ivermectin toxicosis in collies have been reported in several studies (Pullium *et al.*, 1985; Paul *et al.*, 1987; Tranquilli *et al.*, 1987). Ivermectin is a neurotoxicant, as it exerts its toxic effects on the CNS of these sensitive dogs. Further support for CNS involvement was the finding that the ivermectin concentrations in the brain were higher in dogs with P-GP defects displaying signs of ivermectin toxicosis than in dogs with normal P-GP (Pullium *et al.*, 1985). These findings not only suggest involvement of the CNS, but also a difference in the BBB permeability to ivermectin in sensitive versus non-sensitive dogs. However, no differences in the binding characteristics of ivermectin in plasma (albumin and the high density lipoprotein) from ivermectin-sensitive and non-sensitive collies were found (Rohrer and Evans, 1990). The difference between sensitive and non-sensitive dogs lies within the anatomy or physiology of BBB itself or in the presence of high affinity binding sites within the brain rather than difference in the bioavailability of the drug (Kitagawa *et al.*, 1988; Sasaki *et al.*, 1988; Tranquilli *et al.*, 1989). A collie after ingesting ivermectin at about 200 µg/kg (in an equine anthelmintic paste) exhibited the signs of dehydration, bradycardia, respiratory depression, cyanosis, dilated pupils and a diminished gag reflex (Heit *et al.*, 1989). Toxic signs may also include vomiting, ataxia, tremors, hypersalivation, coma and death. Toxic reactions in cats receiving ivermectin (500 µg/kg, SC) include signs such as vocalization, ataxia, tremors, sternal recumbency, coma and death. Young kittens are at increased risk for toxicosis due to increased permeability of their immature BBB. Kittens with ivermectin toxicosis developed signs of mild diarrhea, posterior ataxia and mild miosis (Song, 1991). In contrast, in mammals in which ivermectin does not readily cross the BBB, the drug has a wide margin of safety and at least ten times the therapeutic dose is required to produce toxic effects in most normal mammals (Campbell *et al.*, 1983; Bennett, 1986).

Ivermectin given IV or SC to 8-month-old Jersey bull calves at 600 µg/kg caused depression, ataxia, diarrhea, dyspnea, tachycardia and miosis. Signs were less severe after SC than they were after IV injection. Some of these signs were associated with GABA-mediated cholinergic effects. Calves receiving 8.0 mg/kg developed ataxia and recumbency within 24 h after ivermectin exposure. Calves developed depression, increased respiratory rates, muscular fasciculations, mydriasis and extensor rigidity of the limbs. In cattle, the maximum tolerated dose of B<sub>1a</sub> is about 1.0 mg/kg. With a higher dose of ivermectin in sheep, toxicosis is characterized by depression and incoordination.

Horses exposed to higher doses of ivermectin (six to ten times greater than the therapeutic dose) showed

ataxia, depression and vision impairment within 24 h. With a dose of 60 times the recommended dosage (12 mg/kg), horses showed depression, mydriasis, ataxia, depressed respiratory rate and drooping lower lip (Leaning, 1983).

In an experimental study, Wise *et al.* (1997) demonstrated that at a high dose, emamectin benzoate (derivative of avermectin B<sub>1</sub>) exposure during gestation and lactation in rats produced evidence of neurotoxicity in the F<sub>1</sub> offspring. A no observed adverse effect level for developmental neurotoxicity of emamectin was determined to be 0.6 mg/kg/day.

In acute selamectin poisoning cases, signs of toxicosis may include hair loss at the site of application, vomiting, diarrhea with or without blood, anorexia, lethargy, salivation, tachypnea, pruritis, urticaria, erythema, ataxia and fever. In rare instances, seizures followed by death occur with overt acute overdose. In chronic cases, in dogs and cats, seven monthly treatments of 60 mg/kg (ten times the recommended dose) produced no adverse reactions when given to 6-week-old kittens or puppies. An exposure of 18 mg/kg (three times recommended dose) produced no effect on reproduction in females or males. Three monthly doses of 30 mg/kg produced no adverse effects in ivermectin-sensitive collies. There have also been rare reports of muscle spasms, seizures, ataxia and other neurological signs. In a recent study, dogs treated with a single topical application of Revolution™ (6 mg selamectin/kg body weight) showed no signs of poisoning (Gupta *et al.*, 2005).

## Diagnosis

Diagnosis of ivermectin, selamectin and other MLs can be based on history of exposure to a product, clinical signs and residue analysis in the body tissue or fluids. These compounds are analyzed using high performance liquid chromatograph coupled with a UV, fluorescence or photo diode array detector (Reising *et al.*, 1988; Maynard and Maynard, 1989; Rabel *et al.*, 1993; Payne *et al.*, 1995; Anastaseo *et al.*, 2002; Gupta *et al.*, 2005). GI content, liver, fat and feces are usually the specimens analyzed for MLs residue.

## TREATMENT

Treatment for intoxication with MLs should include limiting systemic absorption of the xenobiotic, monitoring for possible clinical effects and managing any signs that develop. Symptomatic patients should be stabilized prior to performing decontamination procedures. For

oral exposures, emesis, lavage and/or administration of activated charcoal should be considered. If the exposure was by a recent subcutaneous injection and life-threatening toxicosis is possible, surgical excision of the injection site can be considered if the bleb can still be palpated (Beasley *et al.*, 1999).

For patients that can safely vomit, emesis may be effective if performed within 2 hours of ingestion (Mealey, 2006). If the patient is unable to safely vomit (for example, is a species that cannot vomit or is symptomatic), gastric lavage can be considered. Activated charcoal should be considered in addition to or instead of emesis or lavage. It is important to mention that with xenobiotics, like the MLs, which are excreted in the bile, activated charcoal can be of benefit regardless of the route of the exposure. Thus if a patient received an overdose of injectable ML subcutaneously, activated charcoal will still be a very valuable decontamination option. The ML molecules will be carried to the gastrointestinal tract by the bile.

MLs undergo enterohepatic recycling therefore multiple doses of activated charcoal will likely be beneficial. In addition, the MLs are substrates for the p-glycoprotein transport system (P-GP) that transports some drugs across cell membranes. In the intestine, the MLs enter the enterocyte by absorption from the gastrointestinal tract. However, once in the cell, the P-GP acts to move the ML across the membrane and back into the gastrointestinal lumen. This cycling allows the ML molecules to have multiple opportunities to bind with the repeated doses of activated charcoal (Mealey, 2006). When repeated doses are indicated, half the original dose should be given at 4 to 8 hour intervals, often for 2–3 days (Peterson, 2006).

The patient should be monitored for the development of CNS effects including ataxia, lethargy, recumbency, tremors and seizing. Also monitor for bradycardia, gastrointestinal upset and respiratory depression. No specific chemistry panel changes are expected. If activated charcoal is given, serial serum sodium tests should be run to check for elevations as hyponatremia has been associated with repeated doses of activated charcoal.

There is no specific antidote for ML toxicosis so treatment is symptomatic and supportive. Patients who are recumbent or comatose will require good nursing care including thermoregulation, soft bedding and frequent turning to prevent decubital ulcers and urine scalding since the patient may be immobile for multiple days (Mealey, 2006). Patients that are experiencing tremors or seizures can be treated with methocarbamol. Minimize sensory stimuli since these patients can be hyperesthetic. Nutritional support through tube feeding may also be necessary (Mealey, 2006). Intravenous fluids should be given as needed for cardiovascular support and atropine can be used for bradycardia. A respirator may be

necessary if significant respiratory depression develops. Picrotoxin and physostigmine have both been used to treat ivermectin toxicosis but have been associated with significant adverse effects including seizures (Crandell and Weinberg, 2009).

A promising new therapy, intravenous infusion of a lipid emulsion (ILE), has been used to treat moxidectin toxicosis in a puppy (Crandell and Weinberg, 2009). Lipid emulsions are made from purified soybean oil in water, are commonly used in medicine to provide intravenous (parenteral) nutrition and are the delivery mechanism for certain hydrophobic drugs like propofol.

The mechanism by which ILE is effective at treating toxicoses is not yet fully understood. However, the fact that ILE seems to be most effective in treating overdose of lipid soluble medications suggests that the infusion expands the amount of plasma lipid which acts as a sink in which the offending xenobiotic can gather thus reducing free drug concentrations. In theory the xenobiotic is trapped in the plasma lipid so it is not available to act on other tissues (Crandell and Weinberg, 2009; O'Brien *et al.*, 2010).

The ASPCA Animal Poison Control Center uses the following dosing protocol for ILE. Using a 20% product, give an initial bolus of 1.5 ml/kg slowly then start a continuous rate infusion (CRI) of 0.25 ml/kg/min for 30–60 minutes. Four hours after the CRI is finished, check the serum for hyperlipemia and to see if the serum is orange or yellow. If the serum looks normal, repeat the initial bolus and CRI again. If hyperlipemia or a color change is present, check the serum for resolution every 2 hours. Repeat the initial bolus and CRI once the hyperlipemia or color change resolves. If a third dose is needed, follow the above directions beginning 4 hours after the second CRI finishes. Do not give more than three doses if there has been no significant response.

Possible side effects of administering ILE include induction of pancreatitis, creation of a fat embolism, immunosuppression, phlebitis, thrombosis, hypertriglyceridemia and hepatic lipidosis (Crandell and Weinberg, 2009; O'Brien *et al.*, 2010).

## CONCLUSIONS

Macrocyclic lactones (MLs) are commonly used as insecticides, nematicides and acaricides in animals. Among all MLs, acute toxicity is more often encountered with ivermectin. Poisoning occurs in dogs (especially collies) and cats due to inadvertent or misuse of the product meant for another species. In general, young animals are affected with a greater frequency than adults. Clinical signs are those of CNS toxicity. Treatment relies upon symptomatic and supportive therapies.

## ACKNOWLEDGMENTS

One of the authors (RCG) would like to thank Mrs. Robin B. Doss for her assistance in the preparation of this chapter.

# Rotenone

Ramesh C. Gupta

## INTRODUCTION

Rotenone is one of the oldest naturally occurring compounds present in a number of plants. Rotenone is the trivial name of the main chemical component of certain plants of the “Derris,” “*Lonchocarpus*,” “*Tephrosia*” and “*Mundulea*” species. It has a molecular formula of  $C_{23}H_{22}O_6$  and a molecular weight 394.42. Its chemical structure is shown in Figure 52.1. Rotenone is present in the form of colorless crystals, but is readily oxidized by light, and becomes yellow, orange and then deep red. Rotenone and its formulatory products have other names, such as Barbasco, Chem-Fish, Cubé, Cuberol, Derris, FishTox, Haiari, Nicouline, PrenFish, Prentox, Rotacide, SprenFish, Tubatoxin and Tox-R. It is also marketed as Control Garden Dust, Chem-Mite, Cibe Extract, Curex Flea Dust, Derrin and Green Cross Warble Powder. Rotenone is used worldwide because it has broad spectrum insecticidal, acaricidal and piscicidal properties.

Rotenone is also formulated along with other pesticides such as carbaryl, pyrethrins, piperonyl butoxide, lindane and others in products to control insects, mites, ticks, lice, spiders and undesirable fish. In general, rotenone is an excellent organic pesticide used in home gardens for insect control, for lice and ticks on pets, and fish eradications as part of water body management. In veterinary medicine, rotenone is used in powder form to control parasitic mites on chickens and other fowl, and for lice and ticks on dogs, cats and horses. According to a survey conducted by the EPA in 1990, rotenone was found to be one of the pesticides most commonly used in and around the home. During the past decade, rotenone has received enormous attention because of its link

to Parkinson’s disease (Tanner *et al.*, 2011). Rotenone has been found toxic to humans, animals and fish. This chapter describes the toxicity of rotenone in animals.

## BACKGROUND

Emmanuel Geoffroy isolated nicouline (later termed rotenone) for the first time from a specimen of *Robinia nicou*, now called *Lonchocarpus nicou*. Rotenone and rotenoids have been used as crop insecticides since 1848, when they were applied to plants to control leaf eating caterpillars (Ware, 1994). These compounds have been used for centuries (since 1649) in South America to paralyze fish, causing them to surface. Rotenone and rotenoids are extracted mainly from the roots, but also from the seeds and leaves, of certain plants grown in Malaya, East Indies and Central and South America. Presently, Peru is the major source of the root of the plant, which may be ground as a dust or extracted to provide concentrates. Other rotenone-related compounds such as deguelin, tephrosin and toxicarol have been isolated from various parts of rotenone-containing plants, such as legume shrubs. Rotenone has been a registered pesticide in the U.S. under the Federal Insecticide Fungicide Rodenticide Act (FIFRA) since 1947. It is a selective and non-specific insecticide with some acaricidal properties. Its formulations include crystalline preparations (about 95%), emulsifiable solutions (about 50%) and dust (0.75%). Rotenone dust is used for insects, lice and ticks on animals; and beetles and aphids on vegetables, fruits, berries and flowers. Rotenone emulsions are used for eliminating unwanted fish in the management of bodies of water.

FIGURE 52.1 Chemical structure of rotenone.

Rotenone is a very safe compound when properly used, but in higher doses it is toxic to humans, animals and fish. Rotenone has been involved in suicide attempts, in which acute congestive heart failure was the characteristic feature at autopsy. Currently, rotenone is extensively used by researchers as an experimental drug to produce mitochondrial dysfunction and reproduce Parkinson's disease in animal models (Moon *et al.*, 2005; Borland *et al.*, 2008; Watabe and Nakaki, 2008; Drolet *et al.*, 2009). Chronic exposure to rotenone has also been associated with mitochondrial dysfunction, oxidative stress and pathophysiology of Parkinson's disease in humans (Tanner *et al.*, 2011).

## PHARMACOKINETICS/ TOXICOKINETICS

Absorption of rotenone from the gastrointestinal (GI) tract is low and incomplete. In animals, rotenone has been found to be hundreds of times more toxic via the IV route than by the oral route. Fats and oils increase the absorption of rotenone from the GI tract. Rotenone is metabolized in the liver by NADP-linked hepatic microsomal enzymes. Several metabolites have been identified as rotenoids, such as rotenolone I and II, hydroxyl and dihydroxyrotenones, etc. (Hayes, 1982; Gosselin *et al.*, 1984). It has been reported from studies conducted on rats and mice that approximately 20% of a dose is excreted in the urine within 24h of oral administration (Hayes, 1982). Unabsorbed rotenone from the GI tract is excreted in the feces.

## MECHANISM OF ACTION

In insects, rotenone is both a contact and a systemic insecticide. It is used as a broad-spectrum insecticide

that works by inhibiting the transfer of electrons from Fe-S centers in complex I to ubiquinone in the electron transport chain. This prevents NADH from being converted into usable cellular energy, i.e., ATP.

In mammals and fish, rotenone inhibits the oxidation of NADH to NAD, thereby blocking the oxidation of NAD and the substrates such as glutamate,  $\alpha$ -ketoglutarate and pyruvate. In *in vitro* studies, Hayes (1982) demonstrated that the aerobic oxidation of pyruvic acid was completely inhibited by rotenone in isolated rat liver mitochondria. Rotenone causes inhibition of mitochondrial respiratory chain complex I, and cell death by apoptosis due to excess generation of free radicals (Li *et al.*, 2003; Nianyu *et al.*, 2003; Watabe and Nakaki, 2008; MacKenzie *et al.*, 2008). In addition, rotenone causes a definite anesthetic effect when it comes in contact with nerve axons (Hayes, 1982). Following chronic exposure to rotenone, fatty acid synthesis is altered in the mitochondria, resulting in fatty changes in the liver and kidney (Hayes, 1982; Windholz, 1983; Gosselin *et al.*, 1984).

## TOXICITY

Rotenone is a naturally occurring chemical with insecticidal, acaricidal and fish-killing properties. Rotenone is toxic to humans as well as animals. WHO classifies rotenone as a moderately hazardous class II pesticide.

In mammals, the acute toxicity of rotenone is moderate and widely varies between and within species (Ellenhorn and Barceloux, 1988). The oral LD<sub>50</sub> value of rotenone in rats is approximately 60–135 mg/kg body weight, while in mice the value is approximately 350 mg/kg. The LD<sub>50</sub> IP in mice is 2.8 mg/kg. Rotenone is more toxic to female rats than males. Rotenone is less toxic in mice and hamsters than in rats. Pigs seem to be especially sensitive. In rabbits, the LD<sub>50</sub> values for rotenone following IV, oral and dermal routes are 0.35–0.65, 1.5 and 100–200 mg/kg, respectively.

In general, depression and convulsions are the common clinical signs with acute toxicity of rotenone. Following oral ingestion, clinical signs of rotenone toxicosis may include pharyngitis, nausea, vomiting, gastric pain, clonic convulsions, muscle tremors, lethargy, incontinence and respiratory stimulation followed by depression (Hayes, 1982; Gosselin *et al.*, 1984). In animals, severe signs of hypoglycemia and liver failure are evident. Rotenone causes alterations in arterial blood gases and acid-base balance. It induces hypoxemia and hypercapnia due to respiratory depression and seizures. In addition, rotenone can impair myocardial contractile force.

Inhalation of rotenone dust is known to cause severe pulmonary irritation and asphyxia. In rats and dogs, experimental inhalation of rotenone dust produced onset of signs earlier than following oral ingestion (Hayes, 1982). Toxicity is greater if the particles are of smaller size, because these particles can enter the deep regions of the lungs.

Studies suggest that following parenteral administration, rotenone can induce vomiting, incoordination, muscle tremors, clonic convulsions and respiratory failure. Terminal symptoms of rotenone poisoning are convulsions and cardio-respiratory failure (Gosselin *et al.*, 1984; Ellenhorn and Barceloux, 1988). Most often, cardiovascular effects include tachycardia, hypotension and impaired myocardial contractility.

Rotenone is a neurotoxicant. In the rat model, IV infusion of rotenone (2–3 mg/kg/day) is known to produce Parkinson's-like pathology. Both *in vivo* and *in vitro* studies have demonstrated that chronic exposure to rotenone results in degeneration of neuronal cells, especially dopaminergic neurons, and is thereby responsible for the development of the signs of Parkinson's disease (Li *et al.*, 2003; Moon *et al.*, 2005; Watabe and Nakaki, 2008; MacKenzie *et al.*, 2008). The observed neurodegenerative effects are due to inhibition of mitochondrial complex I activity and enhanced production of reactive oxygen species and nitric oxide, leading to excess formation of the toxic factor, peroxynitrite. Chronic rotenone exposure also reproduced Parkinson's disease-like gastrointestinal neuropathology in rats and mice (Drolet *et al.*, 2009; Pan-Montojo *et al.*, 2010).

In a chronic study, dogs receiving rotenone (10 mg/kg/day) for 6 months showed weight loss and hematological changes. Chronic exposure to rotenone may produce fatty changes in the liver and kidney (Windholz, 1983). A no observed adverse effect level (NOAEL) of 0.4 mg/kg/day has been determined in rats and dogs.

Rotenone has no potential for endocrine disruption, but it does have the potential for reproductive toxicity and teratogenicity. Pregnant rats fed 5 mg/kg/day produced a significant number of young with skeletal deformities. In guinea pigs, fetotoxicity has been observed at doses of 4.5 and 9.0 mg/kg/day. Studies suggest that rotenone has no potential to induce mutagenicity (Waters *et al.*, 1982; Moriya *et al.*, 1983). Rotenone may produce tumors in vitamin-deficient animals (Gosalvez, 1983). Its potential to cause carcinogenicity remains controversial.

Rotenone has selective toxicity, as it is highly toxic to fish because of its rapid absorption from the GI tract in comparison to mammalian species in which it is poorly absorbed. The selective toxicity of rotenone in insects and fish versus mammals can also be explained based on the metabolism of this compound. Rotenone converts to highly toxic metabolites in large quantities in insects and fish, while it converts to nontoxic metabolites in mammals.

## Diagnosis

Cases of rotenone poisoning in animals are rare. Diagnosis can be based on circumstantial evidence and detection of rotenone residue in blood, urine, feces and vomitus. It is expected that rotenone residue is more likely to be present in the liver. Rotenone residue can be determined using HPLC coupled with a fluorescence detector or LC-MS-MS (Caboni *et al.*, 2008).

## TREATMENT

There is no specific antidote available for rotenone or rotenoids. Treatment relies upon symptomatic and supportive measures (including oxygen and artificial respiration). Wash contaminated skin to decontaminate rotenone residue. Avoid emesis if convulsions are present or the ingested product has petroleum distillate. Perform gastric lavage, followed by the administration of a slurry of activated charcoal in water. Control seizures and agitation with diazepam and correct hypoglycemia with glucose (5%, IV).

## CONCLUSIONS

Rotenone is widely used as insecticide, acaricide and piscicide, throughout the world. It has selective toxicity, i.e., highly toxic to insects and fish in comparison to mammalian species. Cases of rotenone poisoning in animals are rare. Rotenone causes mitochondrial dysfunction and oxidative stress and cell death occurs by apoptosis. Rotenone is a neurotoxicant and death ensues due to cardiac-respiratory failure. Treatment relies upon symptomatic and supportive therapy.

## ACKNOWLEDGMENTS

I would like to thank Mrs. Robin B. Doss and Ms. Michelle A. Lasher for their assistance in the preparation of this chapter.

# Metaldehyde

Ramesh C. Gupta

## INTRODUCTION

Metaldehyde (2,4,6,8-tetramethyl-1,3,5,7-tetraoxacyclooctane) is a cyclic polymer of acetaldehyde (Figure 53.1), which has a chemical formula of  $C_8H_{16}O_4$  and a molecular weight of 176. It is found in the form of a white or colorless crystalline solid or powder. Metaldehyde is used primarily as a molluscicide to control slugs and snails in a very wide range of gardens and croplands worldwide. Some common slug and snail baits containing metaldehyde include "Cory's Slug and Snail Death," "Deadline" and "Slug-Tox." These products are sold as granules, sprays, dusts, pelleted grain or bait. Metaldehyde is also used in many pesticide products along with other compounds, such as carbamates (carbaryl, cloethocarb or methiocarb), organophosphates and arsenates. Secondary use of this pesticide is for the control of fish, leeches and frogs. Metaldehyde, in combination with a carbamate pesticide, is also applied as a seed dressing in farm crops, such as wheat. In addition, metaldehyde is a main ingredient of solid fuel used for making camp fires (fire starter; camp fuel for portable stove) or in small heaters, and is also marketed as a color flame tablet for party goods (ENGELFIRE). Oral ingestion of metaldehyde in the forms of molluscicides and fuel tablets is the most common source of exposure. Poisoning incidents have been documented in pets (Studdert, 1985; Booze and Oehme, 1985, 1986; Dolder, 2003; Yas-Natan *et al.*, 2007; Campbell, 2008), domestic and wild animals (Harris, 1975; Stubbings *et al.*, 1976; Sutherland, 1983; Fletcher *et al.*, 1999; Valentine *et al.*, 2007; Daniel *et al.*, 2009) and birds (Andreasen, 1993). Poisoning incidents with metaldehyde are most frequently encountered in dogs and cats. Metaldehyde has also been involved in accidents and suicide attempts

(Longstreth and Pierson, 1982; Shih *et al.*, 2004; Bleakley *et al.*, 2008). This chapter describes the toxicity of metaldehyde and its metabolite acetaldehyde in mammalian and avian species.

## BACKGROUND

Metaldehyde has been used as a molluscicide since 1936. Currently, it is the most popular molluscicide used around the world in a variety of vegetables and agricultural crops, greenhouses, gardens and lawns and turf. About 48,000 pounds of metaldehyde are used in the United States each year. It is applied in liquid form, granules, sprays, dusts or pelleted/grain bait to kill slugs, snails and other garden pests. Usually, the commercial baits contain 4% or less metaldehyde as active ingredient. Some of the granule baits can have up to 5–10% metaldehyde. In Europe, the bait can have up to 50% metaldehyde. These products are formulated with a blue or green color. Baits formulated in pellets resemble dog food and are flavored with bran or molasses to attract snails. Unfortunately, the flavor attracts dogs and other pets as well. Acute poisoning is common in pets, birds and domestic and wild animals. A very small amount of metaldehyde is required to cause poisoning or death. The major target organs for metaldehyde toxicity include CNS, liver, kidney and lung. Animals that ingest metaldehyde may exhibit a variety of toxicological signs including vomiting, tachycardia, ataxia, tremors, seizures, coma and death (Dolder, 2003). Upon dermal contact, metaldehyde may cause irritation. Currently, there is an increase in the number

**FIGURE 53.1** Chemical structures of metaldehyde and its two major metabolites (acetaldehyde and acetic acid).

of metaldehyde poisoning cases in dogs attributed to accidental/inadvertent or malicious use of this chemical in baits (Campbell, 2008). This is in spite of the fact that slug baits containing metaldehyde have denatonium benzoate, commonly known as Bitrex (bitter-tasting substance) to help reduce the number of poisonings.

## TOXICOKINETICS

Metaldehyde and its metabolites are readily absorbed from the GI tract. Metaldehyde can also be absorbed from the lungs and skin. Following oral ingestion, maximal concentrations in the circulation and tissues can be attained within 1–3 h. Metaldehyde secretes back into the GI tract because it gets trapped in enterohepatic circulation (Sax, 1984; Dreisbach, 1987; Knowles, 1991). Residues of metaldehyde have been detected in the brain, blood and liver of mice (NLM, 1995; Puschner, 2006).

Metaldehyde undergoes hydrolysis in the acidic pH of stomach, forming acetaldehyde as a major degradation product. Acetaldehyde is then oxidized to acetic acid (Figure 53.1). The half-life of metaldehyde at 24°C is 0.75 and 4 h, in 0.1 and 0.01 mol/L aqueous hydrochloric acid, respectively (Sparks *et al.*, 1996). Following absorption, a significant amount of metaldehyde is metabolized by cytochrome P450. Metaldehyde, but not acetaldehyde, was found in the plasma and urine of dogs given a single oral dose of 600 mg/kg body weight (Booze and Oehme, 1986). Similar findings were reported in a human case (Moody and Inglis, 1992). Metaldehyde can be excreted in urine and feces. Tardieu *et al.* (1996) reported that

only 8% of an oral dose of metaldehyde was excreted as unmetabolized in the urine and feces. Urinary excretion was found to be less than 1% of the oral dose (600 mg/kg, PO) administered to dogs (Booze and Oehme, 1986). Its elimination half-life is reported to be 27 h (Olson, 1999), so its residue does not build up in the body.

## MECHANISM OF ACTION

The pesticidal action of metaldehyde in mollusks and snails is due to direct contact, making them torpid and increasing the secretion of mucus leading to fatal dehydration, convulsions and paralysis (RSC, 1987).

In mammalian and avian species, the toxicity of metaldehyde is characterized by CNS signs, metabolic acidosis and respiratory alkalosis. The exact mechanisms involved are yet to be elucidated. The proposed mechanism of action is that acetaldehyde, which is formed from metaldehyde at a low pH in the stomach, is responsible for the toxic effects observed with metaldehyde exposure (Knowles, 1991). Other toxic products are probably also formed. Metaldehyde and its metabolite acetaldehyde can cross the blood–brain barrier, as evidenced by their neurotoxic effects in animals (NLM, 1995). Acetaldehyde acts as a releasing factor for 5-hydroxytryptamine (5-HT) and norepinephrine. CNS signs of metaldehyde toxicity may be due to decreased brain concentrations of  $\gamma$ -aminobutyric acid (GABA), norepinephrine and 5-HT, as well as increased monoamine oxidase (MAO) activity (Homeida and Cook, 1982a,b; Dolder, 2003). Acetaldehyde competitively inhibits biogenic amine oxidation, which in turn decreases 5-hydroxyindoleacetic acid, a metabolite of 5-HT. Acetaldehyde also increases MAO activity and decreases central 5-HT levels (Booze and Oehme, 1985). The old theory that the toxicity of metaldehyde is attributable to its metabolite acetaldehyde is questionable, because acetaldehyde was not present in the plasma and urine of dogs or the serum of rats that were given metaldehyde (Shintani *et al.*, 1999; Puschner, 2006). Metaldehyde also affects electrolyte and acid–base balances, which can cause metabolic acidosis and respiratory alkalosis that is often associated with central nervous system depression and hyperpnea (Puschner, 2006).

## TOXICITY

Metaldehyde is toxic to all mammals and birds, but not to aquatic life. Secondary poisoning is also not uncommon. Metaldehyde is highly toxic by inhalation, moderately toxic by ingestion and slightly toxic by dermal

absorption. Ingestion is the most common route of poisoning. WHO classifies metaldehyde as a moderately hazardous pesticide, and the EPA classifies it as a slightly toxic chemical (Toxicity Class II or III). This chemical has a label of "Restricted Use Pesticide" because of its potential short-term and long-term effects on wildlife.

The oral LD<sub>50</sub> of metaldehyde is 500mg/kg body weight in dogs, 207mg/kg in cats, 300–400mg/kg in horses, 400–500mg/kg in cattle, 300mg/kg in sheep, 800mg/kg in goats, 400–500mg/kg in pigs, 700mg/kg in rats, 200mg/kg in mice, 500mg/kg in guinea pigs and 1250mg/kg in rabbits (Knowles, 1991; NLM, 1995; Beasley, 1999; Plumlee, 2001). The toxic dose of metaldehyde in dogs and cats is reported to be 45mg/pound of body weight. A minimum lethal dose of 500mg/kg body weight for chicken and 300mg/kg for ducks has been determined. The 96h LC<sub>50</sub> values of metaldehyde in rainbow trout and bluegill are 62ppb and 10ppb, respectively.

The type and severity of signs and symptoms of metaldehyde poisoning varies depending on the amount involved and the nature of the exposure. The most common cause of metaldehyde poisoning is direct ingestion. Metaldehyde is primarily a neurotoxicant, as it produces CNS depression, convulsions and violent muscular contractions in several mammalian species following acute exposure. Acute metaldehyde poisoning is often encountered in pets, especially dogs and cats. Onset of signs of metaldehyde toxicosis usually appear within 15min to a few hours after ingestion. Clinical signs of maximal severity occur within 1–3h of ingestion. In general, toxicity signs of mild metaldehyde poisoning include anxiety, hyperesthesia, foaming at the mouth, vomiting, abdominal pain, diarrhea and muscle twitching. Signs of severe poisoning include hypotension and tachycardia, panting, nystagmus, mydriasis, dehydration, hyperthermia, respiratory depression, convulsions, continuous tonic seizures, coma, ataxia and death due to respiratory failure. Not every poisoned animal may show all these signs, but high fever with muscle twitching is very common. In dogs, hemorrhagic gastroenteritis, hypersalivation and vomiting are also seen. Clinical signs in cats are similar to those described for dogs, but nystagmus is more prevalent in cats (Beasley, 1999).

It is a common observation that exposed pets either die within a few hours from an early episode of acute toxicity or within a few days from liver, kidney and respiratory failure. Symptoms of metaldehyde poisoning in domesticated and wild mammals include inability to stand, blindness, changes in respiratory rate, dehydration, excessive sweating and salivation, seizures and sudden death (Grant and Schuman, 1993).

In cattle, sheep and horses, mild poisoning is evidenced by hypersalivation, ataxia and hyperpnea. In severe poisoning, symptoms include convulsions, sweating, tachycardia and muscle spasms. Death occurs within the first 48 hours of accidental ingestion, and is

attributable to respiratory failure (Von Burg and Stout, 1991). Pathological lesions can be found in the liver, kidney, lungs and GI tract.

Metaldehyde-related poisonings and deaths have been reported in avian species (Baker, 1967; Reece *et al.*, 1985; Andreassen, 1993). A minimal lethal dose of 500mg/kg body weight for chickens and 300mg/kg body weight for ducks has been determined. The clinical signs in avian species include excitability, incoordination, tremors, muscle spasms, torticollis, diarrhea and difficult or rapid breathing. Death of geese and ducks has been observed following accidental exposure. Metaldehyde is considered practically nontoxic to aquatic organisms.

In practical situations, chronic toxicity is very rare. Usually, dosages which are not toxic when given singly do not cause illness when repeated (Dreisbach, 1987; Knowles, 1991). In a 2-year chronic toxicity study (three-generation reproductive studies) in rats, changes in liver enzyme activity and increased liver and ovary weight were found at dietary doses of about 12.5mg/kg/day. Fifty percent of female rats given this dose showed paralysis. At higher doses, metaldehyde is known to adversely affect reproduction and the survival rate of offspring (Sax, 1984). Pregnancy exacerbates the toxicity of metaldehyde.

From experimental studies, there is no evidence that metaldehyde is teratogenic (Verschuren *et al.*, 1975), mutagenic (Quinta and Martire, 1981) or carcinogenic (Verschuren *et al.*, 1975).

## Diagnosis

Diagnosis of metaldehyde poisoning can be established based on a history of exposure and clinical signs. The presence of a blue- or green-colored substance or pieces of metaldehyde bait in the vomitus or GI content can be indicative of metaldehyde exposure. The odor of acetaldehyde in the stomach content is suggestive of metaldehyde exposure. Confirmation and quantitation can be done by determining the metaldehyde/acetaldehyde residue in vomitus or GI tract content, blood or urine (Wardall and Bailey, 1976; Smith, 1987; Keller *et al.*, 1991; Jones and Charlton, 1999; Saito *et al.*, 2008). Laboratory analysis may reveal a mixed metabolic acidosis and respiratory alkalosis. Although pathological findings are nonspecific, lesions can be found in the liver, kidney, lungs and GI tract. Prognosis is usually favorable depending on the amount of metaldehyde ingested and timely treatment.

## TREATMENT

There is no specific antidotal treatment for metaldehyde poisoning. Therefore, treatment rests with supportive

and symptomatic measures that usually consist of: (1) removal of remaining metaldehyde from the GI tract, (2) prevention of absorption by activated charcoal, (3) control of the clinical signs, especially seizures, (4) re-establishing ventilation and administering oxygen and (5) restoring fluid and electrolyte balance to correct acidosis. Administration of 2–5% sodium bicarbonate solution can reduce the conversion of metaldehyde to acetaldehyde.

In the case of dogs, if the patient is asymptomatic, immediately induce vomiting by syrup of ipecac (one teaspoon) or a mixture of hydrogen peroxide and water (one tablespoon), followed by gastric lavage using milk or water. The milk helps decrease further absorption of metaldehyde. Simple osmotic diuresis is helpful. Intravenous fluids are recommended. Administration of activated charcoal (1–4 g/kg, PO) is found to be beneficial, as it prevents further absorption of metaldehyde from the intestines. If necessary, charcoal treatment at half the original dose can be repeated at 6–8 h intervals. Charcoal treatment has been found to reduce absorption of metaldehyde by more than 45% (Shintani *et al.*, 1999). Cathartics can also be used with activated charcoal to assist in removing metaldehyde from the intestinal tract. Gastric lavage and cathartics are found to be an effective treatment for up to 12–24 hours after metaldehyde ingestion. Muscle twitching and spasms in dogs and cats can be controlled by methocarbamol (55–220 mg/kg, IV). Seizures can be treated by using diazepam (0.5–2 mg/kg, IV; repeat if necessary) or sodium phenobarbital (30 mg/kg, IV). Urinary acidosis can be corrected by the administration of sodium bicarbonate. In an experimental study conducted on mice, administration of diazepam (10 mg/kg, IP) or clonidine HCl (0.5 mg/kg, IP) decreased the toxicity of metaldehyde (100 mg/kg, PO). Diazepam at a low dose (0.5 mg/kg body weight) was without any protective effect.

If dogs are poisoned by ingesting a snail bait having metaldehyde along with the carbamate methiocarb, pentobarbitone and atropine should be administered, in addition to other supportive measures (Firth, 1992a, b). In the case of pigs, barbiturates can be used to anesthetize poisoned animals for a period of 6–12 h, so as to allow excretion of metaldehyde and its metabolites.

## CONCLUSIONS

Most often, metaldehyde poisoning is acute in nature and results from accidental or malicious activity. Poisoning is characterized by neurological signs, such as violent convulsions and seizures. Without timely and aggressive treatment, death ensues due to respiratory failure. Since no specific antidote is available, treatment relies upon supportive and symptomatic therapies.

## ACKNOWLEDGMENTS

I would like to thank Mrs. Robin B. Doss and Ms. Michelle A. Lasher for their assistance in the preparation of this chapter.

## Toxicity of herbicides

P.K. Gupta

### INTRODUCTION

Herbicides are phytotoxic chemicals used for destroying various weeds or inhibiting their growth. They have variable degrees of specificity. Some, such as paraquat, kill all green plants, whereas phenoxy compounds are specific for certain groups of plants. The worldwide consumption of herbicides is almost 48% of the total pesticide usage. The consumption of herbicides in developing countries is low because weed control is mainly done by hand weeding (Gupta, 2004). Early chemicals used as herbicides include sulfuric acid, sodium chlorate, arsenic trioxide, sodium arsenate and petroleum oils. Iron and copper sulfate or sodium borate were generally difficult to handle and/or toxic, relatively nonspecific, or phytotoxic to the crop as well as the unwanted plant life if not applied at exactly the proper time. The biochemical differences in plants make it possible to design herbicides that have selective toxicity potential against various species of plants. In approximately the past two decades, the herbicides have represented the most rapidly growing section of the pesticide industry due in part to (1) movement into monoculture practices and (2) mechanization of agricultural practices because of increased labor costs. The result has been a plethora of chemically diverse structures rivaling the innovative chemistry so as to develop synthetic organic herbicides and biopesticides that are quite selective for specific plants and have low mammalian toxicity. The aim is to protect desirable crops and obtain high yields by selectively eliminating unwanted plant species, thereby reducing the competition for nutrients (Gupta, 2006a).

Most of the animal/human health problems that result from exposure to herbicides are due to their improper use or careless disposal of containers (Gupta, 2010a). Very few problems occur when these chemicals are used properly. However, there is increased concern about the effects of herbicides on animal health because of runoff from agricultural applications and entrance into drinking water supply (Gupta, 1986, 1988).

### BACKGROUND

The first discovery in the field of selective weed control was the introduction of 2,4-dinitro-*o*-cresol (DNOC) in France in 1933. This is very toxic to mammals and can cause bilateral cataract in humans. In 1934, phenoxy herbicides were developed and 2,4-dichlorophenoxyacetic acid (2,4-D) was introduced (Gupta, 2010b). During World War II, considerable effort was directed toward the development of effective, broad-spectrum herbicides with a view to both increasing food production and finding potential chemical warfare agents (Gupta, 1989). One chemical class of phenoxy derivatives including the acids, salts, amines and esters represents the first commercially available products evolving from this research in 1946. Some other herbicides used from this class include 4-(2,4-dichlorophenoxy) butyric acid (2,4-DB), 2-(2,4-dichlorophenoxy propionic acid) (dichlorprop), 2-(2-methyl-4-chlorophenoxy) propionic acid (MCPP or mecoprop) and 2-methyl-4-chlorophenoxyacetic acid (MCPA) (Kennepohl *et al.*, 2010). This class of herbicides

has been in continuous, extensive and uninterrupted use since 1947 and is the most widely used family of herbicides. Another chemical class of herbicides deserving particular attention is the bipyridyl group, especially paraquat and diquat. Weidel and Russo first described the structure of paraquat in 1882. In 1933, Michaelis and Hill discovered its redox properties and called the compound methyl viologen. Its herbicidal properties were discovered by ICI in 1955, and it became commercially available in 1962 (Smith, 1997; Lock and Wilks, 2010).

Ureas and thioureas are a group of herbicides used for general weed control in agricultural and non-agricultural practices. The first urea herbicide, *N,N*-dimethyl-*N'*-(4-chlorophenyl)-urea, was introduced in 1952 by DuPont under the common name of monuron. In subsequent years, many more derivatives of this class of compounds have been marketed (Liu, 2010).

Protopyrinogen oxidase (Protox)-inhibiting herbicides have been used since the 1960s and currently represent a relatively large and growing segment of the herbicide market. Nitrofen was the first Protox-inhibiting herbicide to be introduced for commercial use in 1964. This diphenyl ether (DPE) herbicide was eventually recognized as a relatively weak inhibitor of Protox, but it was a lead compound of an entire class of structurally related herbicides that were much more active. Subsequently, several DPE herbicides have been successfully commercialized (Nandihalli *et al.*, 1992; Anderson *et al.*, 1994).

Substituted aniline, an alachlor herbicide, was registered and introduced in 1967 for the pre-plant or pre-emergent control of a broad spectrum of grass, sedge and broadleaf weeds (Heydens *et al.*, 2010). Subsequently, inhibitors of aromatic acid biosynthesis herbicides (organic phosphorus) such as glyphosate, broad-spectrum, nonselective, post-emergent, systemic herbicide with activity on essentially all annual and perennial plants have been developed. Monsanto discovered the herbicidal properties of glyphosate in 1970, and the first commercial formulation was introduced in 1974 under the Roundup brand name. Other triazine and triazole herbicides have been extensively used in agriculture in the United States and other areas of the world for more than 50 years. The triazines inhibit photosynthesis by blocking photosynthetic electron transport (Gysin and Knuesli, 1960; Steven and Summer, 1991; Breckenridge *et al.*, 2010). Dicamba, which was first registered in the United States in 1967, is another organic (benzoic) acid herbicide that acts by mimicking the effects of auxins (i.e., natural plant growth hormones), causing enhanced but uncontrolled growth rates, alterations in plant function homeostasis and death (Harp, 2010). Another class of synthetic chemical compounds called the imidazolinone herbicides was discovered in the 1970s, with the first U.S. patent awarded in 1980 for imazamethabenz-methyl. New families of herbicides

introduced since the 1970s account for increasing shares of use and include bipyridyl (paraquat), bentazon, fenaxalactogen, oxyfluorfen, clomazone, clorpyralid, fluazifop and norfluorazon. Today, the use of newer compounds that have low toxicity is quite common (Osteen and Padgitt, 2002).

## TOXICOKINETICS

Toxicokinetics is associated with the absorption, distribution, metabolism and excretion of drugs and xenobiotics. Toxicokinetics studies provide important data on the amount of toxicant delivered to a target as well as species-, age- and gender-specific metabolism. Animals are exposed to herbicides of different chemical classes. They may be ingested or absorbed through the skin or the respiratory system. Different factors regulate their absorption, distribution, metabolism and excretion (Gupta, 2010b). In general, liver is the primary site for biotransformation and may include activation as well as detoxification reactions through the cytochrome P450-dependent monooxygenase system, the flavin-containing monooxygenase, esterases and a variety of transferases, most notably the glutathione (GSH) *S*-transferases (Hodgson and Meyer, 1997).

2,4-D is the most extensively studied phenoxy acid derivative herbicide. Absorption of 2,4-D occurs rapidly from the gastrointestinal (GI) tract, and peak levels are reached in 10 min to 24 h depending on species, dose and chemical form. Following oral exposure to 2,4-D, plasma half-lives range from 3.5 to 18 h. Dermal absorption was reported to occur rapidly but was usually less than 6%. The compound is protein bound *in vivo* and is rapidly distributed to the liver, kidneys, lung and brain. 2,4-D has also been reported to cross the placental barrier in laboratory animals and pigs. 2,4-D is not metabolized to reactive intermediates, does not accumulate in tissues and is excreted predominantly as the parent compound in urine. However, the rate of excretion via urine is inversely proportional to dose. 2,4-D has been detected in the milk of lactating rats dosed with 2,4-D. The salts and esters of 2,4-D undergo acid and/or enzymatic hydrolysis to form 2,4-D acid, and small amounts may be conjugated with glycine or taurine. Excretion can be markedly enhanced by ion trapping using alkaline agents because most of these herbicides are organic acids (Erne, 1966a,b; Pelletier *et al.*, 1989; Kennepohl *et al.*, 2010).

Another organic acid herbicide, dicamba, is rapidly and nonselectively distributed to most of the organs; however, dermal absorption is minimal. Ninety percent of excretion is through urine, and a small amount is excreted in feces. Dicamba is mostly unmetabolized

but may be conjugated with glucuronic acid or glycine. Elimination occurs rapidly, and there is no evidence of bioaccumulation in the mammalian system (Harp, 2010).

Bipyridyl derivative paraquat is rapidly but incompletely absorbed from the GI tract of laboratory animals and humans, with plasma concentration of 30–90 min, and it is poorly absorbed through contact with skin. It has been reported that dogs absorb more paraquat than do rats, resulting in greater susceptibility of dogs toward paraquat toxicity (Lock and Wilks, 2010). Distribution studies show higher radioactivity in type I and type II epithelial cells and the Clara cells of the rodent and human lungs, which are the major target cells for paraquat toxicity (Smith, 1997). Radioactivity has also been detected in choroid plexus, muscle and melanin in addition to excretory pathways such as the proximal tubules of the kidney, urine, liver, gallbladder and intestinal contents of the mouse, indicating some biliary excretion (Waddell and Marlowe, 1980). Paraquat is taken up into the brain via the neural amino acid transporter; thus, it may be a factor in the etiology of Parkinson's disease. The amount of paraquat excretion in feces corresponds to 60–70% of the ingested dose

(Van Dijk *et al.*, 1975). Paraquat is very poorly metabolized, and bulk is excreted unchanged in the urine and feces. The transport mechanism for organic cations in renal proximal tubular cells is not fully understood; however, two membrane proteins, organic cation transporter 1 (OCT1) and organic cation transporter 2 (OCT2), have been isolated from rat kidney. OCT1, located at the basolateral membrane, transports tetraethylammonium, and this can be inhibited by other organic cations such as quinine. OCT2 stimulates the uptake of tetraethylammonium, and this can be markedly inhibited by cimetidine. The transport of paraquat can be blocked by the addition of the divalent cation quinine, cimetidine and, to a lesser extent, tetraethylammonium, suggesting that paraquat may be transported by both transport systems, an electro neutral organic cation/ $H^+$  exchange and P-glycoprotein (Chan *et al.*, 1998). It was found that the hMATE1-mediated transport of agmatine was inhibited by paraquat, which indicates the involvement of MATE-1 in paraquat renal transport (Winter *et al.*, 2011). It is clear that paraquat can enter a renal cell via OCT2 and, to a lesser extent, OCT1 and then be transported out of the cell by MATE-1 (multidrug and toxin extrusion). However, whether MATE-2k can transport paraquat is not known (Chan *et al.*, 1998; Lock and Wilks, 2010; Winter *et al.*, 2011). A schematic representation of the proposed transport systems for paraquat across renal tubular cells is shown in Figures 54.1 and 54.2.

Unlike paraquat, diquat does not accumulate in the lungs; however, it is observed in liver, kidney, plasma and adrenal gland. Diquat does not enter the brain (Rose *et al.*, 1976). Following oral administration, 90–98% of the dose is eliminated via the urine (Daniel and Gage, 1966). Metabolism studies indicate some unidentified metabolites of diquat in the urine of rabbits and guinea pigs. In rat, diquat monopyridone has been identified in the feces, at approximately 5% of an oral dose, whereas diquat-dipyridone has been detected in urine. These results indicate that diquat is probably metabolized by GI bacteria (JMPR, 1993).

**FIGURE 54.1** Schematic representation of the proposed transport systems for paraquat across renal tubular cells. The transporters are OCT1 and OCT2 at the basolateral membrane and P-glycoprotein and the cation/ $H^+$  exchange system at the brush border membrane. Reproduced with permission from Chan *et al.* (1998).

**FIGURE 54.2** Proposed mechanism of agmatine transport in tissues (i.e., kidney and liver) widely recognized to express OCT1, OCT2 and MATE1. Organic cation transporter (OCT) 1 and 2 mediate the facilitated influx transport of organic cations at the basolateral membrane of hepatocytes and renal proximal tubule cells, respectively. The multidrug and toxic compound extrusion (MATE) transporter 1, an  $H^+$ /cation antiporter, is critical in the efflux elimination of various organic cations from the brush border and canalicular membrane of the kidney and liver, respectively. (Descriptions in parentheses refer to equivalent structures in the liver.) Reproduced with permission from Winter *et al.* (2011)

Ureas and thioureas such as diuron are readily absorbed through the GI tract in rats and dogs and are mainly metabolized by dealkalization of the urea methyl groups. Hydrolysis of diuron to 3,4-dichloroaniline and oxidation to 3,4-dichlorophenol as well as dehydroxylation at carbon 2 and/or carbon 6 of the benzene ring have also been reported. The predominant metabolite of diuron in urine is *N*-(3,4-dichlorophenyl)-urea. Diuron is partially excreted unchanged in feces and urine. The storage of diuron does not occur in tissues (Boehme and Ernst, 1965; Hodge *et al.*, 1967; Liu, 2010).

Organophosphorus herbicides such as glyphosate and glufosinate are poorly absorbed both orally and via the dermal route. There is rapid elimination, and these are not biotransformed and do not accumulate in tissues. More than 70% of an orally administered dose of glyphosate is rapidly eliminated through feces and 20% through urine. The main metabolite of glyphosate is aminomethylphosphonic acid (AMPA); AMPA is of no greater toxicological concern than its parent compound (JMPR, 2004).

The proton class of oxidase inhibitor herbicides is either not readily absorbed or is rapidly degraded by metabolism and/or excreted. The mammalian metabolites are similar to photochemical degradation products. In mammals, there are remarkable species differences in the levels of porphyrin accumulation resulting from exposure to Protox inhibitors. There is no bioaccumulation risk in animals. Metabolism of Protox inhibitors has been studied in a number of species, including rats, rabbits, goats, sheep, cattle and chicken. In general, the metabolic degradation of these compounds by animals includes nitroreduction; deesterification; and conjugation to GSH, cysteine and carbohydrates. Most of the metabolites are excreted in urine, with small amounts excreted in feces and milk. In chickens, approximately 95% of the metabolites are eliminated in excreta, with small amounts (0.09%) eliminated in the eggs (Hunt *et al.*, 1977; Leung *et al.*, 1991).

The carboxyester group of the triazolinone herbicide carfentrazone ethyl is initially metabolized to a carboxylic acid group. Other metabolites identified in rats and lactating goats include hydroxymethylpropionic acid and cinnamic acid derivatives, which are further metabolized to yield a benzoic acid derivative (Aizawa and Brown, 1999).

Substituted anilines are well absorbed in rats orally. The dermal penetration in monkeys is relatively slow. The metabolism of alachlor in rats is complex due to extensive biliary excretion, intestinal microbial metabolism and enterohepatic circulation of metabolites. The main routes of excretion are urine and feces, and nearly 90% of the dose is eliminated in 10 days. The metabolism in rats and mice is similar; however, there are significant quantitative differences between the two species.

These herbicides undergo O-demethylation with the release of formaldehyde; however, the relationship between metabolism-mediated formaldehyde release and nasal tumors induced has not been established. In contrast, alachlor is metabolized in monkeys to a limited number of GSH and glucuronide conjugates, which are excreted primarily via kidney. Excretion in monkeys is more rapid than in rodents, with approximately 90% being excreted in the urine within 48 h. Alachlor metabolites undergo biliary excretion and hepatic circulation in rodents, whereas biliary excretion is limited in monkeys. In rats, acetochlor is rapidly metabolized to several polar metabolites, and more than 95% is quickly excreted in urine and feces. The metabolites are the result of the mercapturic acid pathway formed by initial GSH conjugation. As in the case of alachlor, acetochlor, butachlor and propachlor also undergo glucuronide/glutathione conjugate and enterohepatic circulation leading to tertiary amide methylsulfide metabolite, which further undergoes metabolism in liver and nasal tissue to form the putative carcinogen diethyl quinoneimine (DEIQ) in rats (Millburn, 1975; Feng *et al.*, 1990; Heydens *et al.*, 2010).

Dimethenamid, an amide derivative, is slowly but well absorbed after oral administration (90% in rats) and is extensively metabolized in rats. The maximum concentration in blood is not achieved until approximately 72 h. Excretion is primarily via bile. By 168 h after treatment, an average of 90% of the administered dose is eliminated. In rats, the concentration of radioactivity in blood decreases more slowly than in other tissues and is associated with specific binding to globin (not in humans). Metabolism is primarily via the GSH conjugation pathway, but racemic dimethenamid is also metabolized by cytochrome P450 enzymes via reductive dechlorination, oxidation, hydroxylation, O-demethylation and cyclization pathways, as well as conjugation with glucuronic acid. Unchanged dimethenamid in excreta accounts for only 1 or 2% of the administered dose; more than 40 metabolites have been detected (JMPR, 2005).

In rats, the triazolopyrimidine compounds are rapidly absorbed and urinary elimination is rapid, with half-lives ranging from 6 to 12 h. Excretion is mainly through urine, and small amounts are excreted in feces. The only metabolite present is the 4-OH phenyl derivative and/or oxidation product. In metosulam toxicity, demethylation of the 3-methyl moiety of the phenyl ring and of the 3-methoxy moiety of the pyridine ring and other conjugation products of the parent material have been observed. Other minor metabolites include hydroxylated products of the pyridine ring, although the position of hydroxylation has not been identified. Due to rapid elimination, there is little potential to accumulate in the tissues (Billington *et al.*, 2010).

## MECHANISM OF ACTION

There are a number of biochemical changes or free radical-mediated processes; some may also be produced by other mechanisms that have been used to assess tissue injury. For example, the loss of tissue GSH may reflect alkylation reactions, not oxidation. Furthermore, some free radical-mediated changes that may cause injury are also the result of injury. This is exemplified by the phenomenon of lipid peroxidation that is invoked as a toxic mechanism in many situations but also occurs subsequent to cell death and membrane lysis. In most situations, it is difficult to pinpoint the exact mechanism of action. The mechanism of action of phenoxy derivatives, triazines, triazolopyrimidines, imidazolinones, dinitroaniline and many other classes of herbicides is not precisely known. However, phenoxy compounds are known to depress ribonuclease synthesis, uncouple oxidative phosphorylation and increase the number of hepatic peroxisomes. The relationship of these biochemical changes to clinical effect is not clear. In dogs, these herbicides may directly affect muscle membranes (Sandhu and Brar, 2000). Herbicides such as 2,4-D, 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) and dicamba act as peroxisome proliferators. Oxadiazinon causes hepatic porphyria in both mice and rats. The phenyl urea herbicides linuron and monuron are rodent liver carcinogens. Chloroacetanilide and metolachlor have shown weak hepatocarcinogenicity in female rats and are non-genotoxic, suggesting a tumor-promoting action. The dinitro compounds markedly stimulate respiration while simultaneously impairing adenosine triphosphate synthesis. The main toxic action is uncoupling of oxidative phosphorylation, converting all cellular energy in the form of heat and causing extreme hyperthermia. In addition, the gut flora in ruminants is able to further reduce the dinitro compounds to diamine metabolites, which are capable of inducing methemoglobinemia.

The available information on substituted anilines indicates that there is a nongenotoxic mechanism of action and lack of relevance to humans for the nasal turbinate, stomach and/or thyroid oncogenic effects produced in rats. The data support grouping of alachlor, acetochlor and butachlor with respect to a common mechanism of toxicity for nasal turbinate and thyroid tumors, and grouping of alachlor and butachlor for stomach tumors (Heydens *et al.*, 2010).

The mechanism of action of paraquat and diquat is very similar at the molecular level and involves cyclic reduction–oxidation reactions, which produce reactive oxygen species and depletion of nicotinamide adenine dinucleotide phosphate hydrogen (NADPH). However, the critical target organ differs for the two compounds, so the mammalian toxicity is quite different. Although

both herbicides affect kidneys, paraquat is selectively taken up in the lungs. Paraquat causes pulmonary lesions as a result of type I and type II pneumocytosis. The primary event in the mechanism of toxicity within cells is paraquat's ability to undergo a single electron reduction from the cation to form a free radical that is stable in the absence of oxygen. If oxygen is present, a concomitant reduction of oxygen takes place to form superoxide anion ( $O_2^-$ ). Superoxide radical, in turn, is nonenzymatically converted to singlet oxygen, which attacks polyunsaturated lipids associated with cell membranes to form lipid hydroperoxides. Lipid hydroperoxides are normally converted to nontoxic lipid alcohols by the selenium-containing GSH-dependent enzyme, GSH peroxidase. Selenium deficiency, deficiency of GSH, or excess lipid hydroperoxides allows the lipid hydroperoxides to form lipid-free radicals. Lipid hydroperoxides are unstable in the presence of trace amounts of transition metal ions and decompose to free radicals, which in turn cause further peroxidation of polyunsaturated lipid in a process that is slowed by vitamin E. Peroxidation of the membranes could in turn cause cellular dysfunction and hence lead to cell damage or death (Smith, 1997). Genes associated with oxidative stress, redox cycling and apoptosis have been shown to play a key role in the development of lung fibrosis (Tomita *et al.*, 2007; Lock and Wilks, 2010). The neurotoxicity of paraquat is under debate (Lock and Wilks, 2010). A schematic diagram incorporating these elements of the mechanism of paraquat-induced lung toxicity is shown in Figure 54.3.

The mechanism of action of diquat differs somewhat from that of paraquat because it undergoes alternate reduction followed by reoxidation – a process known as redox recycling. Like paraquat, diquat can redox cycle, with the major difference being that diquat can more readily accept an electron than can paraquat (Gage, 1968). The major target organs are the GI tract, the liver and the kidneys. Unlike paraquat, diquat shows no special affinity for the lung and does not appear to involve the same mechanism that selectively concentrates paraquat in the lung (Rose and Smith, 1977).

Glyphosate, a member of the phosphonomethyl amino acid group, selectively inhibits the enzyme 5-enolpyruvylshikimate 3-phosphate synthetase. The enzyme plays a key role in the biosynthesis of the intermediate, chorismate, which is necessary for the synthesis of the essential amino acids phenylalanine, tyrosine and tryptophan. This aromatic amino acid biosynthesis pathway is found in plants as well as in fungi and bacteria but not in insects, birds, fish, mammals and humans, thus providing a specific selective toxicity to plant species (Franz *et al.*, 1997). Another compound of this group, glufosinate, acts by inhibiting the enzyme glutamine synthetase in animals. Glutamine synthetase in mammals is involved in ammonia homeostasis in many

**FIGURE 54.3** Schematic representation of mechanism of toxicity of paraquat. (1) Structure of paraquat and putrescine; (2) putative accumulation receptor; (3) redox cycling of paraquat utilizing NADPH; (4) formation of hydroxyl radical (OH<sup>•</sup>) leading to lipid peroxidation; and (5) detoxication of H<sub>2</sub>O<sub>2</sub> via GSH reductase peroxidase couple, utilizing NADPH. organs and the glutamine–glutamate shunt between  $\gamma$ -aminobutyrate and glutamate in the central nervous system (CNS). However, the enzyme is normally working at a small fraction of its capacity, and considerable inhibition is required in mammals before ammonia levels increase. Hence, this does not lead to a problem in ammonia metabolism; the mammals obviously compensate by using other metabolic pathways ([Hack et al., 1994](#); [JMPR, 2000](#)).

## TOXICITY

More than 200 active ingredients are used as herbicides; however, some are believed to be obsolete or have been discontinued. Of these, several have been evaluated for their toxic potential, and acceptable daily intake has been recommended by the Joint Meeting on Pesticide Residues ([IPCS, 2002](#)). The herbicides may be classified by their chemical structure, but this is not very informative because of overlapping biological effects of a variety of chemical structures. Herbicides may also be classified based on their use, such as how and when the agents are applied. For example, pre-planting herbicides are applied to the soil before a crop is seeded; pre-emergent

herbicides are applied to the soil before the usual time of appearance of the unwanted weeds. Post-emergent herbicides are applied to the soil after the germination of the crops and/or weeds. Classification may also be based on their mechanism of action in plants; their action is referred to as selective (toxic to some species), contact (direct contact), or translocated (through absorption via the soil or through the foliage into the plant xylem and phloem). The World Health Organization (WHO) has recommended classification of pesticides by their acute hazardous nature. Individual products are classified according to the oral or dermal toxicity of technical products and by their physical state. The comparative toxicity of selected herbicides by hazards along with their LD<sub>50</sub> values in rats are summarized in [Table 54.1](#). These values are intended to serve as only a guide because the toxicity of herbicides may be due to the presence of other ingredients (e.g., surfactants and emulsifiers) present in the formulation. The details of guidelines for their hazard evaluation and their classification have been summarized ([IPCS, 2002](#); [Gupta, 2006b](#)). With a few exceptions, most of the newly developed chemicals have a low order of toxicity to mammals. However, there is increasing experimental and anecdotal evidence that exposure to herbicides also affects at least some form of development and/or reproduction in one or more species of animals. A nonexhaustive list of herbicides that

TABLE 54.1 WHO recommended category (hazardous nature) of major chemical classes of technical-grade herbicides with representative examples of acute LD<sub>50</sub> values in rats

Chemical class	Hazardous class	LD <sub>50</sub> (mg/kg BW)	Chemical class	Hazardous class	LD <sub>50</sub> (mg/kg BW)
<b>Phenoxy acid derivatives</b>			Acetochlor	III	2,950
2,4-D	II	375	Butachlor <sup>b</sup>	U	3,300
2,4,5-T	O	–	Metolachlor <sup>b</sup>	III	2,780

<sup>a</sup>Variable.<sup>b</sup>Liquid.

Ib, highly hazardous; II, moderately hazardous; III, slightly hazardous; U, unlikely to present acute hazard in normal use; O, obsolete or discontinued for use as herbicide.

Compiled from IPCS (2002) and JMPR (2005).

cause developmental toxicity in experimental animals is presented in Table 54.2. Some herbicides have been associated with birth defects in humans. For example, 2,4-D in combination with 2,4,5-T or dioxin, oryzalin, butiphos, picloram, Silvex (2-(2,4,5-trichlorophenoxy) propionic acid) and TCDD (2,3,7,8-tetrachlorodibenzo-*p*-dioxin) are known to cause reproductive problems/malformations in humans. A list of selected herbicides responsible for developmental abnormalities in humans is presented in Table 54.3.

In this chapter, herbicides are classified based on their chemical nature and mechanisms by which they exert biological effects.

**TABLE 54.2** Select herbicides that are known to cause developmental toxicity in experimental animals

Chemical	Malformations
Atrazine	Disruption of ovarian cycle and induced repetitive pseudopregnancy (rats, at high doses)
Buturon	Cleft palate, increased fetal mortality (mice)
Butiphos	Teratogenic (rabbit)
Chloridazon	Malformations
Chlorpropham	Malformations or other developmental toxicity (mice)
Cynazine	Malformations such as cyclopia and diaphragmatic hernia (rabbits); skeletal variations in rats
2,4-D <sup>a</sup> ; 2,4,5-T <sup>a</sup> alone or in combination	Malformations such as cleft palate, hydronephrosis teratogenic (mice, rats)
Dichlorprop	Teratogenic (mice), affect postnatal behavior (rats)
Dinoseb <sup>b</sup>	Multiple defects (mice, rabbits)
Dinoterb	Skeletal malformations (rats), skeletal, jaw, head, and visceral (rabbits)
Linuron	Malformations (rats)
Mecoprop	Malformations (mice only)
Monolinuron	Cleft palate (mice)
MCPA	Teratogenic and embryotoxic (rats); teratogenic (mice)
Prometryn	Head, limb, and tail defects (rat)
Propachlor	Slight teratogenic (rats)
Nitrofen <sup>b</sup>	Malformations (mice, rats, hamsters)
Silvex	Teratogenic (mice)
TCDD <sup>a</sup>	Malformations/teratogenic (fetotoxicity in chickens, rats, mice, rabbits, guinea pigs, hamsters, monkeys)
Tridiphan	Malformations such as cleft palate (mice), skeletal variations (rats)

<sup>a</sup>TCDD is a common contaminant during the manufacturing process of some herbicides, such as 2,4-D and 2,4,5-T.

<sup>b</sup>Obsolete.

Gupta (2011).

## Inorganic herbicides

Substances such as sodium arsenite, arsenic trioxide, sodium chlorate, ammonium sulfamate and borax were formerly used on a large scale. Indeed, the Romans are reputed to have sterilized the soil of Carthage with common salt after the Romans' victory in 146 BC. The disadvantage of such herbicides from an agricultural standpoint is that they are nonselective; thus, their use has declined due to the availability of better and selective organic preparations (Marrs, 2004).

## Phenoxy acid derivatives

This class of herbicides includes 2,4-D, 2,4,5-T, 2,4-DB, dalapon, dichlorprop or 2,4-DP, mecoprop or MCPP, MCPA and Silvex. Some of the phenoxy derivatives are no longer agents of choice because of the formation of chlorinated dibenzofurans and dibenzodioxins, particularly TCDD, as a consequence of poorly monitored manufacturing practices. Some formulations of 2,4,5-T contain dioxin contaminants that increase the toxicity of technical-grade herbicides and therefore the safe use

**TABLE 54.3** Select herbicides responsible for reproductive problems/malformations in humans

Chemical	Location	Year	Malformations
Butiphos	Russia	1970s	Aggravated parturition, congenital malformations and stillbirths
2,4-D plus 2,4,5-T (Agent Orange)	Vietnam	1960s	Miscarriages, stillbirths and congenital malformations
2,4,5-T and dioxin	New Zealand	1970s	Myelomeningocele
Oryzalin	New York	1970s	Miscarriages, stillbirths and heart defects
Picloram	Brazilian state of Para	1984	Miscarriages and malformed fetuses
Silvex	Arizona	1968–1969	Malformations in pets, domestic animals and wildlife, as well as human reproductive toxicity
TCDD	Times Beach, Missouri	1970s	Miscarriages and birth defects

Gupta (2011).

of phenoxy herbicides has been questioned. Published reports have reported the occurrence of three rare forms of cancer (Hodgkin's disease, soft tissue carcinoma and non-Hodgkin's lymphoma) in workers exposed to these herbicides contaminated with dioxins (Kennepohl *et al.*, 2010). However, 2,4-D contains less than the quantitation limits of dioxins set by regulatory agencies (e.g., USEPA). 2,4-D is permitted for use in many countries throughout the world, including the United States and Canada. The structural formulae of selected phenoxy derivatives are given as follows:

2, 4-dichlorophenoxyacetic acid  
(2, 4-D)

2, 4, 5-trichlorophenoxyacetic acid (2, 4, 5-T)

2-methyl-4-chlorophenoxybutyric acid (MCPB)

2-methyl-4-chlorophenoxyacetic acid (MCPA)

A tremendous amount of mammalian toxicity data have been collected during the past 60 years. As a group, these are essentially nontoxic, and acute oral/dermal exposure to phenoxy herbicides is slightly to moderately hazardous in normal use (Table 54.1). Dermal irritation in rabbits is considered slight for the acid form of 2,4-D and minimal for the salt and ester forms. Eye irritation in rabbits, on the other hand, is severe for the acid and salt forms, but it is minimal for the ester. The oral LD<sub>50</sub> for phenoxy acid derivatives in dogs is 100–800 mg/kg body weight (BW). The dog is more

sensitive and may develop myotonia, ataxia, posterior weakness, vomiting, bloody diarrhea and metabolic acidosis because of difficulty in the renal elimination of such organic acids (Gehring *et al.*, 1976). Kidney effects consisting of reduced cytoplasmic eosinophilia of the epithelial cells lining and some convoluted tubules have been reported in dog. 2,4-D does not produce any testicular/ovarian damage or induce any abnormal reproductive disorders. However, some of the molecules of this class have been reported to cause teratogenic effects in animals at maternally toxic doses (Table 54.2) and reproductive problems in humans (Table 54.3). The group of compounds neither induces adverse effects in the nervous and immune systems nor has any potential to induce cancer or mutagenicity in laboratory animals. 2,4-D was found to be noncarcinogenic to rats, mice and dogs (Yano *et al.*, 1991a,b; Munro *et al.*, 1992; Kennepohl *et al.*, 2010).

Phenoxy acid derivatives can potentiate the toxic effects of some toxic plants. They may increase the nitrate content of some plant species and can increase the palatability of certain toxic plants (Sudan grass), thus increasing poisoning risks from these plants. Dogs appear to be the most sensitive animals, whereas sheep, cattle and poultry are less sensitive (Table 54.4).

Animals can tolerate repeated oral doses of phenoxy herbicides without showing significant signs of toxicity; suggesting that there is very little cumulative effect on target organs. At high dosages, two types of clinical symptoms – related to the GI tract and the nervous system – have been observed. GI signs include anorexia, rumen atony, diarrhea, ulceration of oral mucosa, bloat and rumen stasis in cattle and vomiting, diarrhea, salivation, etc. in dogs and pigs. Neuromuscular signs include depression and muscular weakness in cattle and ataxia,

posterior weakness (particularly the pelvic limbs) and periodic clonic spasms (at high doses) in dogs. Silvex is unusual for this group because it is very toxic and small doses (2–6 mg/kg BW) may cause ill effects in dogs (Sandhu and Brar, 2000).

### Bipyridyl derivatives

This chemical class of herbicides includes paraquat (1,1'-dimethyl-4,4'-bipyridylium dichloride) and diquat (1,1'-ethylene-2,2'-bipyridylium dibromide).

Paraquat is usually formulated as dichloride salt (also known as methyl viologen). The bis(methyl sulfate) salt is no longer commercialized. Paraquat is nonselective and is a fast-acting contact herbicide. This compound is the most toxic of the commonly used herbicides, and the toxicity varies in different animals depending on the formulation and species used. The toxic doses (oral LD<sub>50</sub>) of paraquat and diquat in rats are 150 and 231 mg/kg body weight, respectively, and this class of herbicides is classified as moderately hazardous (Table 54.1). Paraquat is a skin and eye irritant but not a skin sensitizer in animals. Mice are less sensitive than rats to orally administered paraquat, whereas guinea pigs, cats, monkeys and rabbits are more sensitive (Murray and Gibson, 1972; Bus *et al.*, 1976a,b; Nagata *et al.*, 1992; Lorgue *et al.*, 1996; JMPR, 2003; Lock and Wilks, 2010). Cattle and sheep are more sensitive than other species. The comparative toxic oral doses of paraquat and diquat in different species are summarized in Table 54.5.

As indicated previously, paraquat and diquat have somewhat different mechanisms of action. Diquat exerts most of its harmful effects in the GI tract. The major cause of death after exposure to paraquat is lung damage. However, rabbits do not show signs of respiratory distress. Immediate toxic effects include convulsions or depression and incoordination, gastroenteritis and, finally, difficult respiration due to pulmonary edema and alveolar fibrosis (2–7 days). Animals that survive the first few days develop dehydration, pallor or cyanosis, tachycardia, tachypnea, harsh respiratory sounds and emphysema or pneumomediastinum.

Upon long-term exposure, there is progressive pulmonary fibrosis and increased respiratory distress. The

morphological changes seen in animals include degeneration and vacuolization of pneumocytes, damage to type I and type II alveolar epithelial cells, destruction of the epithelial membranes and proliferation of fibrotic cells. The animals die as a consequence of reduced gas exchange and the development of severe hypoxia.

Gross lesions include pulmonary congestion, edema and hemorrhages. Lingual ulcers may be seen. Other findings include failure of lungs to collapse when chest is opened and areas of hemorrhages, fibrosis and atelectasis. Microscopic lesions include necrosis of type I alveolar epithelial cells followed by progressive alveolar and intestinal fibrosis and alveolar emphysema. Renal proximal tubular degeneration and moderate centrilobular hepatic degeneration may also be seen (Smith, 1997). In mice, paraquat did not readily cross the placenta, whereas in rats it readily crossed the placenta, being detected in fetuses within 30 min of an intravenous injection to pregnant rats (Lock and Wilks, 2010). It has neither carcinogenic nor mutagenic potential; however, high doses injected into pregnant rats and mice on various days of gestation may cause significant maternal toxicity but do not produce teratogenic effects (Bus and Gibson, 1975).

Diquat is formulated as dibromide salt and is slightly less toxic to dogs than is paraquat (Table 54.5). After chronic exposure, the major target organs are the GI tract, the liver and the kidneys; however, lungs are not affected (Hayes, 1982). The presence of cataracts in both dogs and rats has been observed. Similar signs of toxicity have been seen in mice, guinea pigs, rabbits, dogs and monkeys. Histopathology injuries to the lining of the stomach and GI tract have been observed, but these are not life-threatening (Clark and Hurst, 1970; Cobb and Grimshaw, 1979). Diquat has no effect on fertility, is not teratogenic

TABLE 54.5 TD of bipyridyl derivatives in animals

	Species	mg/kg BW
Paraquat LD <sub>50</sub>	Dogs	25–50
	Cats	35
	Monkeys	50–70
	Cattle	35–50
	Chickens	110–360
	Sheep	8–10

	Cats	35–50
	Cattle	20–40
	Chickens	200–400

Compiled from Lorgue *et al.* (1996).

and produces fetotoxicity only at doses that are maternally toxic. In a multigeneration study, at high doses, cataracts were observed in rats (FAO/WHO, 1993).

## Ureas and thioureas

The ureas and thioureas (polyureas) are available under different names, such as diuron, fluometuron, isoproturon, linuron, buturon, chlorbromuron, chlortoluron, chloroxuron, difenoxuron, fenuron, methiuron, metobromuron, metoxuron, monuron, neburon, parafluron, siduron, tebuthiuron, tetrafluron and thidiazuron. Of these, diuron and fluometuron are the most commonly used in the United States, whereas isoproturon is mostly used in other countries including India.

In general, polyureas have low acute toxicity and are unlikely to present any hazard in normal use, with the exception of tebuthiuron, which may be slightly hazardous (Table 54.1). The comparative toxic values of polyurea herbicides are summarized in Table 54.6.

Diuron and monuron are potent inducers of hepatic metabolizing enzymes compared to those polyurea herbicides with one or no halogen substitutions (chlortoluron and isoproturon). Male rats are more sensitive than females to the enzyme-inducing activity of diuron, and this can lead to detoxication of EPN and O-demethylation of *p*-nitro anisole. N-demethylation of aminopyrine increases for 1–3 weeks and then returns to normal (Hodgson and Meyer, 1997). Recovery from

TABLE 54.6 TD of ureas and thioureas in animals

	Species	mg/kg BW
Diuron TD	Cattle	100 for 10 days
	Sheep	250 or 100 for 2 days
	Chickens	50 for 10 days
Linuron TD	Dogs	100–200
	Cats	35–50
	Cattle	20–40
	Chickens	200–400
Tebuthiuron <sup>a</sup> TD	Cats	200
	Dogs	50 per day for 3 months (anorexia and weight loss reported)

<sup>a</sup>No deaths were reported in dogs, chickens, quail, or ducks at a dosage of 500 mg/kg BW of tebuthiuron.

Compiled from Lorgue *et al.* (1996).

diuron intoxication is quick (within 72 h), and no signs of skin irritation or dermal sensitization have been reported in guinea pigs. After repeated administration, hemoglobin levels and erythrocyte counts are significantly reduced, whereas methemoglobin concentration and white blood cell counts are increased. Dose-dependent relative spleen weight was significantly increased. Increased pigmentation (hemosiderin) in the spleen is seen histopathologically (Liu, 2010). Linuron in sheep causes erythrocytosis and leukocytosis with hypohemoglobinemia and hypoproteinemia, hematuria and ataxia, enteritis, degeneration of the liver and muscular dystrophy. In chickens, it leads to loss of weight, dyspnea, cyanosis and diarrhea. It is nontoxic to fish (Lorgue *et al.*, 1996). Fluometuron is less toxic than diuron. In sheep, depression, salivation, grinding of teeth, chewing movements of the jaws, mydriasis, dyspnea, incoordination of movements and drowsiness are commonly seen. On histopathology, severe congestion of red pulp with corresponding atrophy of the white pulp of the spleen and depletion of the lymphocyte elements have been reported (Mehmood *et al.*, 1995). The acute LD<sub>50</sub> of isoproturon in rats is similar to that of diuron and does not produce any overt signs of toxicity, except at very high doses. A single oral dose of isoproturon in mice may produce some neurotoxic effects at very high doses and may reduce spontaneous and forced locomotor activity (Sarkar and Gupta, 1993a,b).

Polyurea herbicides have been suspected to have some mutagenic effects but do not have carcinogenic potential (Liu, 2010). In general, the compounds do not cause developmental toxicity; however, buturon, linuron and monolinuron are known to cause some teratogenic

Protox inhibitors have little acute toxicity and are unlikely to pose any acute hazard in normal use (Table 54.1). These compounds increase the porphyrin levels in animals when administered orally, and the porphyrin levels return to normal within a few days. Rats and mice are sensitive and variegate porphyria-like symptoms can be generated in mice with high doses of Protox inhibitors. The majority of these compounds are neither mutagenic nor carcinogenic in nature, and the development toxicity correlates with Protox accumulation. Most Protox inhibitors, except bifenox and oxyfluorfen, are non- to moderately toxic to aquatic wildlife (Dayan and Duke, 2010). It has been reported in rats that

prenatal exposure to sulfentrazone leads to neurodevelopmental effects (de Castro *et al.*, 2007).

### Triazines and triazoles

Triazines and triazoles have been used extensively as selective herbicides for more than 50 years. These herbicides are inhibitors of photosynthesis and include both the asymmetrical and the symmetrical triazines. Examples of symmetrical triazines are chloro-*S*-triazines (atrazine, simazine, propazine, terbuthylazine and cyanazine); the thiomethyl-*S*-triazines (ametryn,

prometryn and terbutryn), and the methoxy-S-triazine (prometon) (Breckenridge *et al.*, 2010). The commonly used asymmetrical triazine is metribuzin. The structures of symmetrical and asymmetrical triazines are given as follows:

These herbicides have low oral toxicity and are unlikely to pose acute hazards in normal use, except for ametryn and metribuzin, which may be slightly to moderately hazardous (Table 54.1). They are generally neither irritants to the skin or eye nor skin sensitizers. The exceptions are atrazine, which is a skin sensitizer in guinea pigs, and cyanazine, which is toxic by the oral route. However, sensitivity of sheep and cattle to these herbicides is appreciably high. The main symptoms are anorexia, hemotoxia, hypothermia, locomotor disturbances, irritability, tachypnea and hypersensitivity (Sandhu and Brar, 2000). Doses of 500mg/kg of simazine or 30mg/kg atrazine for 30–60 days are

lethal to sheep. Deaths have been reported in sheep and horses grazing triazine-treated pasture 1–7 days after spraying. Cumulative effects are not seen. Metribuzin is slightly more toxic than simazine, but it does not produce any harmful effects in dogs fed at 100ppm in the diet. Simazine is excreted in milk, so it is a public health concern (Susan, 2003). Atrazine is more toxic to rats but comparatively less toxic to sheep and cattle than is simazine. When cultured human cells are exposed to atrazine, splenocytes are damaged but bone marrow cells are not affected. These herbicides are classified as liver microsomal enzyme inducers and are converted to N-dealkylated derivatives. In contrast to simazine, it is not excreted in milk. Triazines seem to have no potential to be mutagenic or to produce carcinogenicity in animals. However, feeding of very high levels of some triazines resulted in mammary tumors in rats. Terbutryn also caused thyroid and liver tumors in female rats (Breckenridge *et al.*, 2010). The exception is cyanazine, which is more acutely toxic, weak mutagenic, and results in developmental toxicity, presumably because of the presence of cyano moiety (Hodgson and Meyer, 1997).

### Substituted anilines

Substituted anilines are used as systemic herbicides. The commonly used herbicides are alachlor, acetochlor, butachlor, metolachlor and propachlor. The structural formulae of selected ones are as follows:

This class of herbicides is slightly hazardous, except butachlor, which is not likely to pose any hazard (Table 54.1). The compounds are nonirritant to eyes, slight to moderate skin irritant, and produce skin sensitization in guinea pigs. Lower doses in rats and dogs do not produce any adverse effects; however, long-term exposure in dogs causes hepatotoxicity and splenic effects. The ocular lesions (progressive uveal degenerative syndrome) produced by alachlor are considered to be unique to the Long-Evans rat because the response has not been observed in other strains of rats, mice, or dogs. At high oral doses, it may lead to maternal and fetal toxicity but may not cause any adverse effect on reproduction. It is neither teratogenic nor produces any microbial genotoxicity. Alachlor has the potential to produce thyroid tumors and adenocarcinomas of the stomach and nasal turbinates of Long-Evans rats and in the lungs (bronchoalveolar) of CD-1 mice at high doses. It is considered to be a human carcinogen (Ahrens, 1994; Monsanto, 1997a,b; Heydens *et al.*, 2010).

Long-term exposure of acetochlor to rats has no adverse effects on reproductive performance. Acetochlor is converted into a rat-specific metabolite that may be related to the nasal and thyroid tumors, thus posing no genetic or carcinogenic hazard to humans (Ashby *et al.*, 1996). Butachlor does not adversely affect reproductive performance or pup survival. It is nongenotoxic. Butachlor induced multiple tumors in SD rats but not in F344 rats or CD-1 mice (Heydens *et al.*, 2010). Metolachlor can increase the incidence of liver tumors in rats and has been classified as a possible human carcinogen (Monsanto, 1991; Wilson and Takei, 1999; Heydens *et al.*, 2010).

Compared to other substituted anilines, propachlor is severely irritating to the eye and slightly irritating to the skin. Propachlor produces skin sensitization in guinea pigs. In rats, high doses of propachlor produce erosion, ulceration and hyperplasia of the gastric mucosa; herniated mucosal glands in the pyloric region of the stomach; hypertrophy; and necrosis of the liver. In dogs, there is poor diet palatability, which results in weight loss and poor consumption of food. Propachlor may produce slight development or adverse reproductive effects (Table 54.2). It is not genotoxic or clastogenic in mammals. However, there is evidence that it produces benign hepatic tumors in male mice (Heydens *et al.*, 2010). The previously discussed data support grouping alachlor, acetochlor and butachlor based on a common mechanism of toxicity for evaluation of risk assessment to humans and animals (Heydens *et al.*, 2010).

## Amides and acetamides

The commonly used amides and acetamides include bensulide, dimethenamid-P and propanil and are

slightly to moderately hazardous in normal use (Table 54.1). Dimethenamid is a racemic mixture of the M and P stereoisomers, whereas P isomer has useful herbicidal activity. Both substances produce only mild reversible skin and eye irritation and skin sensitization in guinea pigs. Comparison of racemic dimethenamid with dimethenamid-P indicates that there is little difference in their toxicological profiles. The signs of toxicity in mice, rats and dogs are similar, with reduced body weight gain and liver enlargement with induction of liver xenobiotics metabolizing enzyme. There is strong binding to hemoglobin in rats, but this has no relevance to humans. Dimethenamid-P and racemic dimethenamid produce very similar effects in the liver of rats. Both substances produce neither any signs of neurotoxicity nor adverse effects in developmental toxicity or on reproductive performance. Dimethenamid can reduce fetal body weight but is not teratogenic. There is no compound-related mutagenic or carcinogenic potential (JMPR, 2005).

## Dinitrophenol compounds

Several substituted dinitrophenols alone or as salts, such as DNP (2,4-dinitrophenol), DNOC (dinitro-*o*-cresol) and dinoseb (2-(1-methylpropyl)-4,6-dinitro), are used as herbicides. The main source of poisoning in animals is human negligence in removing the preparation if it spills, in disposing of the containers and in preventing animals access to treated fields. The structural formulae of DNP, DNOC and dinoseb are as follows:

In general, the dinitro compounds are not very water-soluble and are highly hazardous to animals (Table 54.1). The oral acute LD<sub>50</sub> of DNOC in mice, guinea pigs, rabbits, hens, dogs, pigs and goats ranges

TABLE 54.7 TD of DNOC and dinoseb in animals

	Species	mg/kg BW
DNOC		
LD <sub>50</sub>	Hens	26
	Dogs	50
	Pigs	50
	Goats	100
TD	Cattle	2–50
	Sheep	20–50
LD	Sheep	25 for 5 days
Dinoseb		
LD <sub>50</sub>	Hens	26
TD	Cattle	25 for 8 days
	Sheep	25 for 10 days

Compiled from Lorgue *et al.* (1996).

from 25 to 100 mg/kg BW. (Table 54.7). In sheep, a dosage of 25 mg/kg/day causes toxicosis in 2–5 days. Clinical signs include fever, dyspnea, acidosis, oliguria, muscular weakness, tachycardia and convulsions followed by coma and death with a rapid onset of rigor mortis. Abortions have been reported in sows. In cattle and ruminants, methemoglobinemia, intravascular hemolysis and hemoproteinemia have been observed. Cataract can occur with chronic dinitrophenol intoxication. Exposure to these compounds may cause yellow staining of skin, conjunctiva, or hair (Lorgue *et al.*, 1996).

## Triazolopyrimidine herbicides

Triazolopyrimidine herbicides include cloransulam-methyl, diclosulam, florasulam, penoxsulam, flumetsulam, metosulam and pyroxsulam. The generic structure of the triazolopyrimidine herbicides connected to a substituted phenyl ring through a sulfonamide bridge is

shown here. The substituents of the various members of this class are summarized in Table 54.8.

Generic structure of the triazolopyrimidine herbicides

The acute oral toxicity of triazolopyrimidine herbicides is very low. On repeated exposure, the primary organs are the kidney (rat and mouse), liver (rat, mouse and dog) and thyroid (rat). Slight decreases in red cell parameters and urine-specific gravity in males, slightly increased cecal and liver weights, slight to moderate hypertrophy of collecting renal tubule epithelial cells and/or slight vacuolization of proximal tubular epithelium, hepatocellular vacuolation, and slight thyroid follicular hypertrophy have been observed (Billington *et al.*, 2010). In most cases, the histopathological changes represent adaptive responses. Analysis of <sup>14</sup>C activity of dog eyes indicated that this organ is a target of toxicity in dogs, exhibiting an affinity for the radiotracer not seen in other species (Timchalk *et al.*, 1996). No adverse effects on neurotoxicity, reproductive performance and mutagenic abnormalities have been observed. The compound has no carcinogenic potential in humans (EPA, 1997a,b).

## Imidazolinones

Imidazolinone herbicides include imazapyr, imaza-methabenzmethyl, imazapic, imazethapyr, imazamox and imazaquin. These are selective broad-spectrum

TABLE 54.8 Substituents of triazolopyrimidine sulfonamide herbicides

From Billington *et al.* (2010).

herbicides discovered in the 1970s. The structural formulae of this class of herbicides are as follows:

These herbicides are relatively nontoxic (Table 54.1). Results from primary eye irritation studies range from no irritation (imazaquin) to slightly irritating (imazamethabenzmethyl) and moderately irritating (imazapic and imazethapyr), showing complete recovery within 7 days post-dosing. The rabbit primary irritation study with imazapyr showed irreversible irritation. Toxicological effects of imidazolinone herbicides are slight to moderate skeletal myopathy and/or slight anemia in dogs occurring in the 1-year dietary toxicity studies with three structurally similar imidazolinones (imazapic, imazaquin and imazethapyr). There is no evidence of any adverse effect on reproductive performance and on fetal abnormalities in the rat and the rabbit. Neither mutagenicity nor any carcinogenicity has been reported in either of these species (Hess *et al.*, 2010).

### Benzoic acids

The herbicides in this group include chloramben, dicamba and naptalam. These have a low order of

toxicity, and the LD<sub>50</sub> values in rats are summarized in Table 54.1. The structural formulae of selected herbicides are as follows:

In practice, dicamba is often combined with other herbicides and is used to control a wide spectrum of weeds. The signs and lesions are similar to those described for the chlorophenoxy acids. Poisoning after normal use has not been reported in domestic animals. Dicamba either alone or combined with another herbicide induced significant levels of apoptosis in mouse preimplantation embryo assay (Greenlee *et al.*, 2004). It is a skin and eye irritant, and high doses may cause neurobehavioral symptoms in rats and rabbits. The compound did not show any adverse effects in a three-generation study in rats (Harp, 2010).

Dicamba induces peroxisomal enzymes in rat liver and causes transcription up-regulation of the peroxisome proliferator-activated receptor. Long-term exposure to dicamba may induce tumors in rats due to its action as a peroxisome proliferator; however, the implications of these findings are not clear and may require further study (Espandiari *et al.*, 1998). Dicamba-induced oxidative stress-mediated cytogenotoxicity has been demonstrated in an *in vitro* cell model (Gonzalez *et al.*, 2009; Harp, 2010).

### Carbamates, thiocarbamates and dithiocarbamate compounds

The compounds in this category include derivatives of carbamic acid (asulam, barban, chlorpropham, chlorbulfam, karbutilate and phenmedipham), derivatives of thiocarbamic acid (butylate, cycloate, di-allate, EPTC,

TABLE 54.9 TD of asulam and di-allate in animals

	Species	mg/kg BW
Asulam LD <sub>50</sub>	Rabbits	>2000
	Chickens	>2000
	Dogs	>5000
Di-allate LD <sub>50</sub> TD	Dogs	510
	Chickens	150 for 10 days or 250 for 7 days
	Cattle	25 for 5 days or 50 for 3 days
	Sheep	25 for 5 days or 50 for 3 days

Compiled from Lorgue *et al.* (1996).

molinate and tri-allate) and derivatives of dithiocarbamic acid (metham sodium). These herbicides have low to moderate toxicity in rats and do not pose acute hazards (Table 54.1). They are used at low concentrations, and poisoning problems have not been reported. In general, these herbicides do not produce skin or eye irritation. With repeated exposure, there is a possibility of alopecia for some time after ingestion (Lorgue *et al.*, 1996; Hurt *et al.*, 2010). The toxic doses of asulam and di-allate in animals are summarized in Table 54.9.

In ruminants, di-allate results in anorexia, ataxia, muscular contractions, exhaustion, prostration and alopecia in sheep, which is an indication of chronic poisoning. Thiobencarb has induced toxic neuropathies in neonatal and adult laboratory rats. It appears to increase permeability of the blood–brain barrier. The nonspecific lesions include hepatic, renal and pulmonary congestion; enteritis; ascites; and hydrothorax (Susan, 2003).

## Others

Bromacil and terbacil are commonly used methyluracil compounds. These compounds can cause mild toxic signs at levels of 50 mg/kg BW in sheep, 250 mg/kg BW in cattle and 500 mg/kg BW in poultry when given daily for 8–10 days. Signs of toxicity include bloat, incoordination, depression and anorexia. Toxic doses of bromacil can be hazardous, especially for sheep, but no field cases of toxicity have been reported (Table 54.10).

The nitrile herbicides, ioxynil and bromoxynil, may uncouple and/or inhibit oxidative phosphorylation. Ioxynil, presumably due its iodine content, causes enlargement of the thyroid gland in the rat (Marrs, 2004). Members of polycyclic alkanolic acids (diclofop, fenoxaprop, fenthiaprop, fluazifop and haloxyfop) have moderately low toxicity, whereas haloxyfop-methyl is an exception, having high toxicity. They tend to be more toxic if exposure is dermal. The dermal LD<sub>50</sub> of diclofop in rabbits is only 180 mg/kg (Susan, 2003). Some

TABLE 54.10 TD of bromacil in animals

Species	mg/kg BW
Cattle	250
Chickens	500 for 10 days
Sheep	50 for 10 days or 250 for 8 days

Compiled from Lorgue *et al.* (1996).

members of the amide group, such as bensulide and propanil, are used as plant growth regulators, and some of them are more toxic than others (Table 54.1). A lethal dose of bensulide for dogs is 200 mg/kg.

The prominent clinical sign is anorexia; other signs and lesions are not definitive and are similar to those of chlorophenoxy acid poisoning. Hemolysis, methemoglobinemia and immunotoxicity have occurred after experimental exposure to propanil (Lorgue *et al.*, 1996). The toxicity of sulfonylureas (chlorsulfuron, sulfometuron, metsulfuron, chloremuron and kensulfuron) appears to be quite low (Susan, 2003).

A number of substances are used as defoliant in agriculture, including sulfuric acid to destroy potato haulms and two closely related trialkylphosphorothioates (DEF and merphos) to defoliate cotton. A notable feature of the latter is that they produce organophosphate-induced delayed neuropathy in hens (Baron and Johnson, 1964). Chlomequat is used as a growth regulator on fruit trees. The signs of toxicity in experimental animals indicate that it is a partial cholinergic agonist (JMPR, 2000).

## ENDOCRINE DISRUPTION

In both males and females, some herbicides affect reproduction through different mechanisms of action of endocrine disruption; exogenous agents interfere with reproduction and the development process. In males, normal reproductive function involves interaction of the hypothalamic–pituitary–testis axis and the thyroid gland. In females, increased concentrations of xenoestrogens may affect ovarian function through the disruption of feedback mechanisms in the hypothalamus–pituitary–gonadal axis (Flaws and Hirshfield, 1997; Bretveld *et al.*, 2006). Herbicides, like other chemicals, may disrupt all stages of hormonal function of the reproductive system. In females, during pregnancy and, to a greater extent, during lactation, a portion of the maternal body burden of these chemicals is transferred to the offspring. For example, herbicides such as linuron produce hypothyroidism (Gupta, 2011). The herbicide glyphosate in low nontoxic concentrations caused disruption of the

aromatase enzyme in human placental cells *in vitro*. It reduced the aromatase enzyme activity responsible for the synthesis of estrogens (Richard *et al.*, 2005). A study indicated that male reproductive toxicity of glyphosate is due to the inhibition of a StAR protein and an aromatase enzyme, which caused an *in vitro* reduction in testosterone and estradiol synthesis. The study further suggested that commercial formulation of glyphosate (glyphosate-Roundup Transorb, Monsanto) is a potent endocrine disruptor *in vivo* because it caused disturbances in the reproductive development of rats when the exposure was performed during the puberty period (Romano *et al.*, 2010). From various experimental studies, it has been concluded that herbicides can disturb reproduction and development processes of both males and females through endocrine signals in organisms indirectly exposed during prenatal or early postnatal life. Such effects during fetal development may be permanent and irreversible.

According to one estimate, eight herbicides (2,4-D, 2,4,5-T, alachlor, amitrole, atrazine, metribuzin, trifluralin and nitrofen) were identified as endocrine disruptors. Most of these were identified accidentally rather than as a result of an exhaustive screening process (Pocar *et al.*, 2003).

## TREATMENT

The successful management of herbicide poisoning depends on (1) the clinicians' understanding of the mechanism of herbicide toxicity and applying that understanding to the treatment options, (2) accurate diagnosis and assessment of the severity of intoxication, (3) maintenance of vital body functions and adequate clinical monitoring, (4) minimization of further absorption of the compound, and (5) appropriate use of specific treatment. Because the majority of herbicides have relatively low acute and chronic toxicity, no attempt has been made to identify antidotes for intoxication. However, there is a great deal of controversy regarding the purported chronic effects of phenoxy derivatives such as 2,4-D and 2,4,5-T due to the potential for contamination of 2,4,5-T with the highly toxic and unwanted byproduct commonly referred to as dioxin. Treatment is usually symptomatic and supportive. Intravenous fluid should be given to promote diuresis. Similarly, there is no specific treatment for bipyridyl herbicide poisoning. The therapy for bipyridyl poisoning may focus on prevention of absorption from the GI tract. Paraquat binds tightly to diatomaceous clay. Oral administration of adsorbents such as bentonite or Fuller's earth (clay) along with a cathartic such as magnesium sulfate may be

helpful. Toxicity of paraquat is enhanced by selenium/vitamin E deficiency, oxygen and low tissue GSH peroxidase activity. Therefore, vitamin E and selenium with supportive therapy may be useful in the early stages of intoxication. Excretion of bipyridyl compounds may be accelerated by forced diuresis induced by mannitol infusion and furosemide administration. Oxygen therapy and fluid therapy are contraindicated (Clark, 1971; Smith *et al.*, 1974). Dinis-Oliveira and co-workers experimentally found dexamethasone, sodium salicylate and lysine acetylsalicylate to be an effective treatment for paraquat-induced toxicity. Furthermore, they concluded that the antioxidant properties of these agents might be responsible for their effectiveness (Dinis-Oliveira *et al.*, 2006, 2007, 2008, 2009).

An effective antidote for dinitrophenol compounds is not known. Affected animals should be cooled and sedated to help control hyperthermia. Phenothiazine tranquilizers are contraindicated; however, diazepam can be used to calm the animal. Atropine sulfate, aspirin and antipyretics should not be used; rather, physical cooling measures such as cool baths or sponging and keeping the animal in a shaded area are advocated. Intravenous administration of large doses of sodium bicarbonate (in carnivores) solutions, parenteral vitamin A and intense oxygen therapy, where possible, may be useful. If the herbicide is ingested and the animal is alert, emetic should be administered; if the animal is depressed, gastric lavage should be performed. Treatment with activated charcoal should follow. Dextrose-saline infusions in combination with diuretics and tranquilizers (not barbiturates) are very useful. In ruminants, for methemoglobinemia, methylene blue solution and administration of ascorbic acid are useful (Lorgue *et al.*, 1996).

## CONCLUSIONS

Herbicides are routinely used to control noxious plants. Most of these chemicals, particularly the synthetic organic herbicides, are quite selective for specific plants and have low toxicity for mammals; other less selective compounds (e.g., arsenicals, chlorates and dinitrophenols) are more toxic to animals. Most animal health problems including reproduction, which is affected by endocrine disruption, result from exposure to excessive amounts of herbicides because of improper or careless use or disposal of containers. The residue potential for most of these chemicals is low. However, some aspects of herbicidal toxicity, such as the isozyme specificity for metabolism, induction and inhibition in interaction of herbicides with hepatic P450, flavin-containing monooxygenase-dependent oxidations, and phase I and

phase II enzymes, need special attention because these are not clear. A number of other questions remain unanswered, such as; What interactions occur at portals of entry and sites of toxic action? Can this information help us to understand the mechanism of action? In addition, during reproduction, physiological changes occur in virtually every maternal organ/system. These changes may have a profound effect on the toxicokinetics of the chemical. For example, 2,4,5-T is more slowly eliminated in mice as gestation progresses due to increased tissue residence, resulting in potentially higher fetal exposure during the later stages of pregnancy. Indeed, clearance of chemicals from the developing fetus appears to be progressively decreased during gestation in rats. It is therefore a challenge to predict maternal or embryo/fetal exposure at various times during pregnancy. A good understanding of pregnancy-related anatomical and physiological changes in animals and their potential impact on the chemical kinetic is required.

## Toxicity of fungicides

*P.K. Gupta and Manoj Aggarwal*

### INTRODUCTION

Fungicides are agents that are used to prevent or eradicate fungal infections from plants or seeds. In agriculture, they are used to protect tubers, fruits and vegetables during storage or are applied directly to ornamental plants, trees, field crops, cereals and turf grasses. Numerous substances having widely varying chemical constituents are used as fungicides (Gupta, 1988). Fungicides have been classified according to chemical structures or have been categorized agriculturally and horticulturally according to the mode of action (Ballantyne, 2004). According to the mode of application, fungicides are grouped as foliar, soil and dressing fungicides. Foliar fungicides are applied as liquids or powders to the aerial green parts of plants, producing a protective barrier on the cuticular surface and systemic toxicity in the developing fungus. Soil fungicides are applied as liquids, dry powders, or granules, acting either through the vapor phase or by systemic properties. Dressing fungicides are applied to the postharvest crop as liquids or dry powders to prevent fungal infestation of the crop, particularly if stored under less than optimum conditions of temperature and humidity. Thus, effective fungicides must be protective, curative, or eradivative and should possess the following properties: (1) low toxicity to the plant/animal but high toxicity to the particular fungus; (2) activity *per se* or the ability to convert themselves (by plant or fungal enzymes) into toxic intermediates; (3) the ability to penetrate fungal spores or the developing mycelium to reach the site of action; (4) low ecotoxicity; and (5) the ability to form a protective, tenacious deposit on the plant surface that will be resistant

to weathering by sunlight, rain and wind (Phillips, 2001). With a few exceptions, most of the newly developed chemicals have a low order of toxicity to mammals. Public concern has focused on the positive mutagenicity tests obtained with many fungicides and the predictive possibility of both teratogenic and carcinogenic potential. The quantity of fungicides used on major crops is estimated to have increased 2.3-fold between 1964 and 1997. Use of inorganics (primarily copper compound) and dithiocarbamates has declined since the 1960s, but captan, chlorothalonils and other organic materials account for 90% of fungicide use. Newer groups, such as benzimidazoles, conazoles, dicarboximides and metal organic compounds, account for approximately 10% of fungicide use (Osteen and Padgitt, 2002). In this chapter, fungicides are discussed using a chemical classification system.

### BACKGROUND

The earliest fungicides were inorganic materials such as sulfur, lime, copper and mercury compounds. The use of element sulfur as a fungicide was recommended as early as 1803. It has become an important component of integrated pest management systems because it can be used in "organic farming." There are an increasing number of instances of dermatitis in human farmworkers and diseases in ruminants caused by exposure to high levels of sulfur (Gammon *et al.*, 2010). The mercury-containing fungicides have been responsible for many deaths or permanent neurological disability. Some of the earlier

inorganic metallic fungicides have been withdrawn in many countries because of their toxicity and adverse environmental effects (Ballantyne, 2004). Another compound, hexachlorobenzene (HCB), was extensively used from the 1940s through the 1950s as a fungicidal dressing applied to seed grains as a dry powder. Between 1955 and 1959, an epidemic of poisoning occurred in Turkey and resulted in a syndrome called black sore and caused more than 4000 deaths. Although this agent has largely fallen by the wayside, it is still being used in developing countries. It is a highly toxic compound and can lead to severe skin manifestations including hypersensitivity (Hayes, 1982; Gupta, 2010a). Since that time, many compounds have been developed and used to control fungal diseases in plants, seeds and produce. Carbamic acid derivatives, including ethylenebisdithiocarbamates (EBDCs), are a group of fungicides that have been used widely throughout the world since the 1940s. The important members of this class include mancozeb, maneb, metiram, zineb and nabam. All the members have an EBDC backbone, with different metals associated with the individual compounds. Captan, folpet and captan-fol have been in use for more than 55 years. These compounds belong to the chloroalkylthiodicarbimide class of fungicides due to the presence of chlorine, carbon and sulfur in the side chain. Related compounds associated with this fungicide class are dichlofluanid and tolylfluanid. These two compounds have a fluorine atom substituted for one of the terminal chlorine atoms. Another compound, chlorothalonil, which is a halogenated benzonitrile fungicide, was first registered for use as an agrochemical in the United States in 1966. Chlorothalonil also has wider biocidal applications, including use in paints and lubricant fluids. The benzimidazole fungicides, benomyl and carbendazim, have been in use for more than 40 years, whereas anilinopyrimidines, a new class of fungicides (cyprodinil, mepanipyrim and pyrimethanil), were introduced in 1993 (cyprodinil by Ciba in France) for application on cereal grains (Ollinger *et al.*, 2010).

## TOXICOKINETICS

Toxicokinetic studies provide important data on the amount of toxicant delivered to a target as well as species-specific metabolism. Animals are exposed to fungicides through ingestion or they are absorbed through the skin or the respiratory system. Different factors regulate their absorption, distribution, metabolism and excretion. In general, the liver is the primary site for biotransformation and may include detoxification as well as activation reactions (Gupta, 1986). Some fungicides do not undergo

any metabolism and bind with other active binding sites. The aryl organomercurials methyl- and ethylmercury chloride are poorly excreted and tend to accumulate in muscle, brain and other tissues, whereas the aryl organomercurial phenylmercury is more readily excreted via the kidney and less likely to accumulate in brain and muscles. Similarly, HCB possesses all the properties of chemical stability, slow degradation and biotransformation, environmental persistence and bioaccumulation in adipose tissue and organs containing a high content of lipid membranes (Costa, 2008). The newly introduced class of fungicides are rapidly absorbed, metabolized and excreted and do not accumulate in tissues, but some of them are partially absorbed from the gastrointestinal (GI) tract. For example, absorption of chlorothalonil from the GI tract is on the order of 30–32% of the administered dose. At least 80% of the administered dose is excreted in feces within 96 h. The highest concentrations are observed in the kidneys – approximately 0.1% of the dose. In this case, gut microflora play a role in the disposition and metabolism in rats. Glutathione conjugation plays a central role in the metabolism and subsequent complex metabolic processing of these conjugates, resulting in selective renal uptake and urinary excretion of thiol-derived metabolites. Hepatic glutathione levels are decreased, and renal glutathione levels are elevated. The depletion of hepatic glutathione is considered a direct consequence of glutathione conjugation within the liver utilizing tissue resources. The increase in renal glutathione content is more difficult to explain, but it may be a consequence of urinary excretion of glutathione conjugates (Parsons, 2010).

The captan is rapidly degraded to 1,2,3,6-tetrahydrophthalimide (THPI) and thiophosgene (via thio-carbonyl chloride) in the stomach before reaching the duodenum. THPI has a half-life of 1–4 s, and thiophosgene is detoxified by reaction with cysteine or glutathione and is rapidly excreted. No captan is detected in blood or urine. It is therefore unlikely that these compounds or even thiophosgene would survive long enough to reach systemic targets such as the liver, uterus, or testes. Due to rapid elimination, meat, milk, or eggs from livestock/poultry would be devoid of the parent materials. Humans appear to metabolize captan in a similar manner to other mammals (Krieger and Thongsinthusak, 1993; JMPR, 2004; Gordon, 2010).

Cyprodinil, an anilinopyrimidine class fungicide, is rapidly absorbed from the GI tract into systemic circulation in rats. Approximately 48–68% of the administered dose is excreted in the urine, whereas 29–47% is found in the feces. Total excretions reach 92–97% of the administered dose within 48 h. Cyprodinil is almost completely metabolized. No unchanged parent molecule is found in urine, whereas minor amounts of unchanged cyprodinil are found in feces. Most of the administered cyprodinil

FIGURE 55.1 Phase I metabolism of cyprodinil in rats. Reproduced with permission from Waechter *et al.* (2010).

is metabolized by sequential oxidation of the phenyl and pyrimidine ring (Figure 55.1). In urine and feces, there is no difference in the metabolite patterns of the phenyl or pyrimidyl labeled cyprodinil. Seven urinary, two biliary and two fecal metabolites have been identified, which in total account for 65–80% of the administered dose. Cyprodinil is absorbed in goats to a lesser extent and more slowly than in rats. The major route of excretion is in urine and feces, whereas excretion via milk is minimal. In laying hens, cyprodinil is rapidly and completely eliminated. Residues in eggs and edible tissues are very low. The metabolic pathways of cyprodinil in lactating goats and laying hens are similar to those observed in rats (Figure 55.1) (Waechter *et al.*, 2010).

Carbamic acid derivative fungicides, such as EBDCs, are only partially absorbed, and then they are rapidly metabolized and excreted with no evidence of long-term bioaccumulation. Absorption of oral doses is rapid, and doses are excreted within 24h with approximately half eliminated in the urine and half in the feces. Their common metabolite is ethylenethiourea (ETU). Only

low-level residues are found in tissues, particularly the thyroid. Another compound in this class, propamocarb, is rapidly and nearly completely absorbed and distributed with a concentration reaching peak levels within 1h. Elimination from tissues is rapid; with a half-life ranging from 11 to 26h, urine is the main route of excretion (~75–91% within 24h). Up to 6% of the administered dose is excreted in feces. Propamocarb is extensively metabolized, and only small quantities are unchanged in urine. Metabolism involves aliphatic oxidation of the propyl chain (to form hydroxyl propamocarb) and N-oxidation and N-demethylation of the tertiary amine resulting in propamocarb N-oxide and mono demethyl propamocarb, respectively. Both benomyl and carben-dazim are well absorbed after oral exposure (80–85%) but poorly absorbed after dermal exposure (1 or 2%) in rats, mice, dogs and hamsters. The major pathway of clearance is urinary elimination in rats and mice, but in dogs the majority of the dose (83.4%) is eliminated via feces, with only 16.2% of the dose eliminated in the urine after 72h of dosing. In animals, benomyl is converted

into carbendazim through the loss of the *n*-butylcarbamy side chain prior to further metabolism. In dogs and rats, carbendazim undergoes aryl hydroxylation–oxidation at the 5 and 6 positions of the benzimidazole ring, followed by sulfate or glucuronide conjugation before elimination. The urinary excretion half-life of carbendazim in both male and female rats is approximately 12h. Benomyl or carbendazim or their metabolites are cleared rapidly from blood and exhibit minimal potential for bioaccumulation in rats exposed orally or intravenously (Gardiner *et al.*, 1974; JMPR, 2005).

Similarly, amide fungicides are rapidly absorbed and eliminated. Metalaxyl-M and metalaxyl can lead to stimulation of hepatic and renal cytochrome P450 and some other drug metabolizing enzymes. Tolyfluanid is rapidly and extensively absorbed, followed by rapid metabolism and almost complete excretion, mainly in the urine and to a lesser extent in the bile, within 48h. High tissue concentration has been seen soon after dosing in the kidney and liver, with lower concentrations in the perirenal fat, brain, gonads and thyroid. In most species, the concentration of fluoride in the bone and teeth increases in a dose-related manner (JMPR, 2002, 2005).

After oral dose, conazole fungicides such as triadimenol and triadimefon are rapidly absorbed and widely distributed in liver and kidney. Excretion and metabolism is rapid and extensive, predominantly through oxidation of the *t*-butyl methyl group. Propiconazole indicates rapid and extensive absorption (80% of the administered dose) and is widely distributed, having the highest concentration in liver and kidney. Excretion is more than 95% in the urine and feces within 48h. There is extensive enterohepatic recirculation. The compound is extensively metabolized with oxidation of propyl side chain, hydroxylation of phenyl and triazole rings, and conjugation. The cleavage of dioxolane is significantly different according to species and sex (JMPR, 2004). The other compound, fludioxonil, is rapidly and extensively (80%) absorbed, widely distributed, extensively metabolized and rapidly excreted, primarily in feces (80%), with a small amount being excreted in the urine (20%). The maximum blood concentration is reached within 1h after administration. Elimination is biphasic, with half-lives of between 2 and 5h for the first phase and between 30 and 60h for the second phase. The compound is extensively metabolized, involving primarily oxidation of the pyrrole ring (57% of the administered dose) and a minor oxo-pyrrole metabolite (4% of the administered dose), followed by glucuronyl and sulfate conjugation. There is no potential of accumulation in the tissues. Trifloxystrobin is rapidly absorbed (66%) in 48h and is widely distributed, with highest concentrations in blood, liver and kidney. Within 72h, 72–96% of the administered dose is eliminated in the urine and feces. Metabolism is extensive, and the compound undergoes

hydroxylation, O-demethylation, oxidation, conjugation, chain shortening and cleavage between glyoxyphenyl and trifluoromethyl moieties (JMPR, 2004).

## MECHANISM OF ACTION

There are a series of biochemical changes or free radical-mediated processes; some may also be produced by other mechanisms that have been used to assess tissue injury. This is exemplified by the phenomenon of lipid peroxidation, which has been invoked as a toxic mechanism in many situations and also occurs subsequent to cell death and membrane lysis. However, in most situations, it is difficult to identify the exact mechanism of action. For example, in fungicides containing mercury, the mercury ions inhibit the sulfhydryl group of enzymes involved in the transfer of amino acids across the blood–brain barrier and then interfere with protein synthesis. Organomercurials can also release some mercury ions in the body, but their toxicity is not believed to be a primary action of mercury ions (Sandhu and Brar, 2009). There are several theories regarding the mechanism by which sulfur produces its toxic action. The oxidized sulfur theory attributes toxicity to its oxidation products, such as sulfur dioxide, sulfur trioxide, thiosulfuric acid, or pentathionic acid. The reduced sulfur theory ascribes toxicity to hydrogen sulfide. Direct action theory suggests toxicity due to crosslinking of proteins, formation of other cellular components by free radicals of sulfur or polysulfides, or extensive oxidation of thiol groups leading to loss of function or structural integrity of proteins. Pentachlorophenol (PCP), a halogenated substituted monocyclic aromatic, acts cellularly to uncouple oxidative phosphorylation, with the target enzyme being  $\text{Na}^+/\text{K}^+$ -ATPase. Oxygen consumption is increased, whereas adenosine triphosphate (ATP) formation is decreased. The energy is lost as heat instead of being stored as high-energy phosphate bonds. The electron transport chain responds by using increasingly more available oxygen (increased oxygen demand) in an effort to produce ATP, but much of the free energy is lost as body heat. This leads to depletion of energy reserves (Eaton and Gallagher, 1997). Similarly, organotin compounds, particularly triethyltin, uncouple oxidative phosphorylation, whereas other agents (e.g., sulfur) in the presence of sulfiting agents such as sulfur dioxide uncouple oxidative phosphorylation. Thiamine is cleaved into its constituent pyrimidine and thiazole moieties, rendering it inactive.

Although the biochemical and molecular mechanism(s) by which captan and its analogs exert their cellular toxicity has not been fully established, captan is known

FIGURE 55.2 Mode of action for captan and folpet in the mouse duodenum. Reproduced with permission from Gordon (2010).

to react with cellular thiols to produce thiophosgene, a potent and unstable chemical capable of reacting with sulfhydryl-, amino-, or hydroxyl-containing enzymes (Cremlyn, 1978). Thiols reduce the potency of captan. A volatile product of captan is responsible for mutagenic activity, the intermediate being short-lived and formed more quickly at higher levels at an alkaline pH. There are several other mechanisms by which these chemicals can induce cellular toxicity. For example, mouse tumors develop with oral administration above a threshold if maintained for at least 6 months. As shown in Figure 55.2, epithelial cells that comprise the villi are damaged by exposure to captan and sloughed off into the intestinal lumen at an increased rate. Second, the basal cells in the crypt compartment that normally divide at a rate commensurate with the normal loss of villi cells from the tips of the villi increase, resulting in high cell proliferation, which is not carcinogenic per se but does play a role in tumor development. However, there appears to be no treatment-related duodenal tumor incidence of captan in rats or dogs. Some of the data have been compiled in reviews, and a task force and framework have been evolving for evaluation of the mode of toxicity and tumorigenicity findings in mice bioassay and human relevance for risk assessment purposes (Arce *et al.*, 2010; Cohen *et al.*, 2010; Gordon, 2010).

Chlorothalonil fungicide is a reactive molecule toward thio (–SH) groups. It is a soft electrophile with a

preference for sulfur nucleophiles rather than nitrogen/oxygen nucleophiles. Such chemicals tend to show reactivity toward protein containing critical S electrophiles rather than toward DNA (containing critical O and N nucleophiles). A mechanistic interpretation for the carcinogenicity of chlorothalonil has been published by Wilkinson and Killeen (1996). Repeated administration of chlorothalonil causes hyperplasia in the forestomach of rats and mice. The data are consistent with a temporal sequence of events starting with increased cell proliferation, multifocal ulceration and erosion of the forestomach mucosa, regenerative hyperplasia and hyperkeratosis, and ultimately progressing to the formation of gastric tumors within the forestomach. In dogs, there is no evidence of either neoplastic development or the occurrence of pre-neoplastic lesions in the kidney or stomach. The absence of stomach lesions in dogs is attributable to the anatomical differences between rodents and dogs – dogs do not possess a forestomach. Continued administration of chlorothalonil leads to the development of a regenerative hyperplasia within the renal proximal tubular epithelium. Continued regenerative hyperplasia ultimately results in progression of the kidney lesion to tubular adenoma and carcinoma. Initial cytotoxicity and regenerative hyperplasia within the proximal tubular epithelium are essential prerequisites for subsequent tumor development. The proposed mode of action for the induction of renal toxicity in rodents is outlined in Figure 55.3.

**TABLE 55.1 WHO recommended categories (hazardous nature) of major chemical classes of technical-grade fungicides with representative examples of LD<sub>50</sub> values in rats**

Chemical class	Category	LD <sub>50</sub> (mg/kg BW)

Ia, extremely hazardous; Ib, highly hazardous; II, moderately hazardous; III, slightly hazardous; U, unlikely to present acute hazard in normal use; O, obsolete or discontinued; c, variability; d, dermal. Compiled from IPCS (2002) and JMPR (2005).

had been in use throughout the 19th and early 20th centuries. Elemental sulfur and crude lime sulfur (calcium polysulfide and barium polysulfide) are commonly used as fungicides. The most notable chemical property of sulfur is its tendency to spontaneously oxidize. This property is responsible for sulfur's effects on the eyes, skin and respiratory tract. Safety concerns presented by combustion of sulfur can be mitigated by avoiding its use during periods of high ambient temperature. In general, the use of sulfur does not present a toxicological problem. Only micronized sulfur is responsible for sulfur poisoning. Lethal doses are as follows: cattle, 100–1000 mg/kg body weight (BW); sheep, 1000–1500 mg/kg BW; and horses, 1000–1500 mg/kg BW. The most affected animals are cattle, sheep, goats and dogs. In ruminants, excessive sulfur ingestion may lead to polioencephalomalacia, which is also called cerebrocortical necrosis. It involves softening of gray matter of the brain. Sulfur poisoning may lead to GI tract, neurological and pulmonary effects. On postmortem, congestion of the stomach and intestine, hemorrhagic effusions and petechiae along the GI tract and occasionally on the surface of the bladder have been observed (Jensen *et al.*, 1956; Low *et al.*, 1996; Gammon *et al.*, 2010). Negative effects in humans, especially on the skin, eyes and respiratory tract, have been reported (Gammon *et al.*, 2010). Currently, its use has declined due to the availability of organic fungicides. Another fungicide, barium polysulfide, after reaction with gastric acid yields barium chloride, which is a super purgative (Lorgue *et al.*, 1996; Ballantyne, 2004; Sandhu and Brar, 2009).

## Metallic fungicides

Inorganic metallic fungicides were first used in agriculture. They are protective and preventive. Mercuric and mercurous compounds have been withdrawn because of their toxicity. Ethylmercury phosphate, 2-methoxyethylmercury chloride, phenylmercury chloride and phenylmercury acetate are used as seed treatments for cereals and fodder beet (Lorgue *et al.*, 1996). Cattle, sheep and pigs are the most affected species. Oral LD<sub>50</sub> ranges from 10 to 500 mg/kg BW, depending on the species and the particular compound involved. The organic metallic fungicides are both aliphatic and aromatic. Many are of moderate to high mammalian toxicity, with several being immunotoxic and neurotoxic. Livestock exposed to mercurials may develop central nervous system (CNS) and skin changes. The CNS signs include incoordination and ataxia, body swaying followed by prostration, convulsions and death. CNS stimulation is seen in calves, dogs, cats, rats and humans. However, other species (adult cattle, swine and fowls) manifest CNS depression. Other signs associated with organomercurials are

TABLE 55.2 Select fungicides that cause development toxicity in experimental animals

Chemicals	Malformations
Ammonium salts, manganese and zinc	Multiple defects (rats)
Benomyl	Skeletal malformations, increased mortality (rats), multiple anomalies (mice), small renal papillae but no malformations (rabbits)
Bis(tri- <i>n</i> -butyltin)oxide	Cleft palate and development toxicity (rats, mice)
Bitertanol	Tail, palate, jaw, eye defects (rat)
Captan	CNS, rib, tail and limb defects (hamsters); no teratogenic effects in other four species
Carbendazim	Multiple defects, CNS and rib (rabbits, hamsters)
Conazoles	Limb malformations, postnatal behavior alterations, postural reflex, open field behavior (rat)
Cycloheximide <sup>a</sup>	Variable multiple defects <sup>c</sup>
Dinocap <sup>b</sup>	Skeletal defects, dactyly, hydrocephaly or other development defects
EBDCs (maneb and zineb metabolites, monosulfide and ETU)	Multiple malformations, hyprocephaly (rabbit)/experimental teratogen
Fenpropimorph	Multiple malformations and embryo–fetotoxic effects
Ferbam	Development toxicity and malformations
Fusilazole	Soft tissue and skeletal (rats)
Hexachlorobenzene	Multiple malformations
Mancozeb	Variety of defects, renal and palate (hamsters, mice), rib variation and reduced weight (rats)
Methylmercury	Variety of defects
Polycarbacin	Multiple malformations and embryotoxic
Prolineb	Embryotoxic, malformations
Propiconazole	Multiple malformations
Thiram	Development toxicant
Triadimenol	Multiple malformations
Triadimefon	Developmental toxicity
Tridemorph	Scapula malformations (rabbits)
	Cleft palate, other malformations and development toxicity (rats, mice)

TABLE 55.3 Select fungicides responsible for reproductive problems/malformations in humans

Chemical	Locations	Years	Reproductive abnormalities
Methylmercury	Japan, New Mexico, Iraq, Sweden and Russia	1953 and subsequent years	Disrupts CNS developmental processes in the unborn and infantile
Benomyl	England and Wales	1990s	Tetramelia, eye defects, miscarriages, premature delivery and infants with congenital anomalies
Captan alone and/or with other pesticides	England	1990s	Miscarriages, premature delivery and infants with congenital anomalies
Hexachlorobenzene	Turkey	1955–1957	Stillbirths and neonatal mortality
Zineb		1970s	Reproductive problems

From Gupta (2011).

bronchopneumonia, hyperpyrexia, epistaxis, mucous membrane hemorrhages, hematuria and bloody feces. Skin lesions include eczema, pustules, ulceration, keratinization, dehydration, weakness and death (Sandhu and Brar, 2009). Typical organotin compounds are di- and trialkyl and triphenyl tins. In general, they are severely irritant to the

skin, eyes and mucosae, and several are hepatorenotoxic and immunotoxic. They have been shown to increase susceptibility to infection, decrease lymphopoiesis and decrease T lymphocyte production. Trialkyl tins cross the blood–brain barrier and are centrally neurotoxic (WHO, 1990).

### Halogenated substituted monocyclicaromatics

This class of chemicals includes chlorothalonil, dicloran, HCB, quintozene, PCP, dichlorophen, dinocap, tecnazene and chloroneb. Chlorothalonil is a nontoxic halogenated benzonitrile fungicide (Table 55.1). Dermal irritation has been observed following repeated exposure in the rat and rabbit, indicating the potential for chlorothalonil to cause skin irritation. Chlorothalonil causes irreversible and severe ocular lesions in rabbits. Signs of toxicity include decreased body weight and decreased hematological parameters, increased absolute kidney weight, vacuolar degeneration in the proximal tubular epithelium and hyperplasia of the forestomach. Chlorothalonil is not genotoxic *in vivo*. Treatment-related increase in renal tubular adenoma and carcinoma, squamous cell adenoma and carcinomas of the forestomach of both species have been reported. Chlorothalonil is not a developmental or reproductive toxicant when tested up to doses that cause significant maternal toxicity and maternal death; however, a significant increase in the incidence of postimplantation loss due to early embryonic death has been observed (Parsons, 2010). Tecnazene has an oral rat  $\text{LD}_{50}$  of 2047 mg/kg BW and is a mild irritant in the rabbit eye. The compound has the potential to produce pulmonary adenoma, but it is neither embryotoxic nor teratogenic in mice (Ballantyne, 2004). Chloroneb, quintozene and dicloran have low toxicity (Table 55.1), and dinocap is a moderate eye irritant and has a human skin sensitizing potential. HCB, like other organochlorine compounds, possesses all the properties of chemical stability, slow degradation and biotransformation with potential to accumulate in adipose tissues and organs containing a high content of lipid membranes, and it has the ability to induce a range of tissue cytochrome P450 as well as conjugate enzymes. Repeated exposure in animals results in hepatomegaly and porphyria as well as focal alopecia with itching and eruptions, followed by pigmented scars, anorexia and neurotoxicity expressed as irritability, ataxia and tremors. The compound can

increase hepatic and thyroid tumors in hamsters and is teratogenic in mice (renal and palate malformations) and in rats (increased incidence of 14th rib). HCB is also toxic to developing perinatal animals (Table 55.2) and causes adverse effects on the immune system (Costa, 2008). PCP has oral rat  $\text{LD}_{50}$  of 150–210 mg/kg BW. Common signs of toxicity are increased breathing rate, increased temperature, tremors, convulsions, loss in righting reflex and asphyxial spasms. Corneal injury may result from splashes or vapor overexposure. Toxicity is more often due to contamination of commercial-grade PCP. Technical-grade PCP causes hepatic porphyria, increased microsomal monooxygenase activity and increased liver weight. Lethal dose in cattle and sheep is in the range of 120–140 mg/kg BW. Chronic toxicity leads to emaciation, weight loss, reduced productivity (milk, eggs, meat, etc.) and increased mortality in poultry (ATSDR, 1994; Lorgue *et al.*, 1996).

### Chloroalkylthiodicarboximides (phthalimides)

This class of chemicals contains broad-spectrum fungicides (captan, folpet, captafol, etc.) used as surface protectants on many crops. They are usually nontoxic to mammals. The oral  $\text{LD}_{50}$  in rats is as follows: captan, >9000 mg/kg BW; folpet, >10,000 mg/kg BW; and captafol, >5000 mg/kg BW (Table 55.1). However, a low-protein diet makes the animal more sensitive. Of this class of chemicals, folpet and captafol, which are true phthalimides, have been deregistered; only captan, being structurally different (see structural formulae) with a cyclohexene ring, is being used. The compound is a severe eye irritant because of its high reactivity. Folpet induces incidences of diarrhea, vomiting, salivation, reduced food intake and reduced body weight gain. Testes weights are reduced in dogs. A single dose applied to the skin results in mild to low irritation. Long-term exposure to rats causes hyperkeratosis and acanthosis of the esophagus and stomach, particularly

after folpet exposure. Among ruminants, cattle are the most affected, and captan produces toxicity (oral TD, 250–500 mg/kg BW) with labored respiration, anorexia, depression, hydrothorax, ascites and gastroenteritis (Sandhu and Brar, 2009). Mutagenicity may be associated with these agents *in vitro* at exceptionally high doses required to elicit biological effects. These compounds degrade extremely rapidly in the presence of thiols, with a plasma half-life of only a few seconds. However, duodenal tumors in mice have been reported, which were considered to be due to the irritation potential of compounds to the GI tract of rats (Gordon, 2010). Some compounds of this class cause developmental effects (Table 55.2), whereas others are not proven because of, and/or masked by, maternal toxicity and possible nutritional deficits (Costa, 2008). Captan induces hyperplasia of the crypt cells. Following

treatment with folpet, immune function is reduced, villi length is reduced and crypt compartments are expanded, thereby reducing the villi-to-crypt ratio in mice (JMPR, 1990; Tinston, 1995; Waterson, 1995; Gordon, 2010). The most characteristic pathologic finding consists of necrotizing and proliferative changes in the nonglandular portion of the stomach, dilation of the small intestine and focal epithelial hyperplasia in the proximal part of the small intestine in mice following treatment with captan (Gordon, 2010). Captafol differs from captan and folpet in a number of ways, including structure and chemical activity. Both of them have low acute toxicity. They are not carcinogenic, mutagenic, or teratogenic. They are neither selective developmental toxins nor reproductive toxins. They are an irritant of mucus membranes, especially of skin after repeated exposures (Gordon, 2010).

## Anilinopyrimidines

The anilinopyrimidine class of fungicides includes cyprodinil, mepanipyrim and pyrimethanil. The compounds have low toxicity and are unlikely to present acute hazards in normal use (Table 55.1). Cyprodinil produces hepatomegaly with hepatocellular hypertrophy and increased thyroid weights associated with follicular cell hypertrophy and hyprochromasia in rats. Subchronic exposure also resulted in kidney lesions in rats. The compound also causes single cell necrosis in male mice and depletion of glycogen in female mice, whereas in dogs, increased blood platelets have been observed at high doses. Mepanipyrim causes hepatocellular fatty vacuolation and lipofuscin deposition in Kupffer cells and hepatocytes of dogs, whereas such changes are not observed in cyprodinil-treated rats (Terada *et al.*, 1998). Pyrimethanil produces thyroid follicular cell tumors in rats and enhancement of hepatic thyroid hormone metabolism, which may be responsible for thyroid tumorigenesis (Hurlety, 1998). The findings in the thyroid were considered to be secondary to liver changes. Enhancement of hepatic thyroid hormone metabolism and excretion are considered to be the mode of action of thyroid tumorigenesis (Hurlety, 1998; Waechter *et al.*, 2010). Cyprodinil induced microsomal protein and cytochrome P450 contents along with ethoxyresorufin *O*-deethylase, pentoxyresorufin *O*-deethylase and lauric acid 11- and 12-hydroxylase, as well as cytosolic glutathione *S*-transferase activities in rats (Waechter *et al.*, 2010). Generically, cyrodinil and mepanipyrim induce the opposite effects on liver and blood lipid parameters in rats. In general, anilinopyrimidines do not have adverse effects on development toxicity. They are neither genotoxic nor have any carcinogenic potential (Waechter *et al.*, 2010).

## Carbamic acid derivatives

The carbamic acid class of fungicides includes dithiocarbamates (ferbam, thiram, ziram, propamocarb, etc.) and EDBC (maneb, mancozeb, zineb, nabam, metiram, etc.). In general, carbamic acid derivatives, except nabam, have low or moderate acute toxicity by the oral, dermal and respiratory routes (Table 55.1). The main features of toxicity include anorexia, diarrhea and flatulence followed by neurological effects, ataxia, muscular contractions and prostration. With repeated ingestion, there is a possibility of cutaneous effects, alopecia and a risk of antithyroid effects, especially with maneb. Certain compounds inhibit ovulation and egg laying (thiram and ziram). On histopathology, hepatic, renal and pulmonary congestion is common. Occasionally, hepatic degeneration, ascites, enteritis and hydrothorax have been observed (Lorgue *et al.*, 1996). Propamocarb is non-irritating to the eyes or skin. It induces sensitization in a Magnusson-Kligman maximization test. The signs of toxicity include hypokinesia, lethargy, hunched posture, body tremors, clonic convulsions, nasal hemorrhages, piloerection, staggering gait and ataxia. Vacuolar changes in various tissues including choroid plexus in the brain and reduction in organ weights have been observed in the rat and dog. Common development and reproductive abnormalities include reduction in copulation index (female rats) and body weight, retardation in ossification (rat) and increased postimplantation loss (rabbit) (JMPR, 2005). The principal target organ upon repeated exposure to EDBC is the thyroid. These fungicides alter thyroid hormone levels and/or weights. The developmental toxicity includes malformations and embryo-fetotoxic effects at maternally toxic dose levels with EBCs in rats (Table 55.2) (Ollinger *et al.*, 2010).

## Benzimidazoles

The major benzimidazole fungicides include benomyl, carbendazim and fuberidazole. Benomyl and carbendazim have low toxicity, whereas fuberidazole has moderate toxicity (Table 55.1). Both benomyl and carbendazim produce reproductive and developmental toxic effects in laboratory animals at high oral doses (Table 55.2). Reproductive toxic effects include decreased sperm count, decreased testicular weights and histopathological changes, whereas developmental toxic effects include reduced fetal weight and anomalies of eyes (microphthalmia or anophthalmia), skull and head (hydrocephaly). The effects observed on the oocytes and uterine weight in female rats are direct and are not mediated by endocrine changes (Jeffay *et al.*, 1996; Spencer *et al.*, 1996). A high dose of carbendazim causes an increased incidence of diffuse proliferation of parafollicular cells of the thyroid in female rats. Both of these compounds are not carcinogenic in rats; however,

lifetime exposure in mice shows benign (not malignant), hepatocellular neoplasms and adenomas. Carbendazim is a developmental toxicant and teratogen (JMPR, 2005).

## Conazoles

The conazole class of fungicides includes cyproconazole, diniconazole, triadimefon, triadimenol, propiconazole and imazalil and has low to moderate acute toxicity (Table 55.1). Triadimenol is triazole, and triadimefon is closely related chemically to triadimenol, with increasing toxicity for increasing isomer A ratios (isomer B is less toxic). Triadimenol is non-irritating, whereas technical-grade triadimefon is sensitizing. The other symptoms of toxicity include liver toxicity and CNS effects (general restlessness, alternating phases of increased and reduced motility, and aggressive behavior). Liver adenomas have been observed in female mice. Developmental toxicity indicates increased ovary and testes weights, increased

Benomyl

Carbendazim

Fuberidazole

supernumerary lumbar ribs with triadimenol and increased scapula malformations at maternal toxic doses in rabbits after triadimefon (JMPR, 2004). Propiconazole is not an eye irritant in rabbits, but it is irritating to rabbit skin and a skin sensitizer in guinea pigs. The compound causes reduction in body weight, liver toxicity and adverse changes in erythrocytes (rat) and the stomach (dog). On long-term exposure, liver hypertrophy and tumors (mice), uterine lumen dilation (rats), developmental toxicity indicative of reduced pup weight at parentally toxic dose and skeletal variations in laboratory animals have been observed (JMPR, 2004).

## Morpholines

The class of morpholine fungicides includes dodemorph, fenpropimorph and tridemorph. Dodemorph and fenpropimorph are unlikely to cause acute hazards, whereas tridemorph is moderately hazardous (Table 55.1). Dodemorph acetate is moderately irritating to rabbit skin and a severe irritant to rabbit eye. Fenpropimorph is a mild irritant to rabbit skin, whereas tridemorph is non-irritant. Tridemorph and fenpropimorph lead to developmental toxicity (Table 55.2), with an increase in the total number of malformations (JMPR, 2004).

Cyproconazole

Diniconazole

Triadimefon

Triadimenol

Propiconazole

Imazalil

## Amides

Commonly used amide fungicides are fenhexamid, benalaxyl, metalaxyl, flutolanil, tolylfluanid and dichlofluanid. The compounds are of low toxicity, except for metalaxyl, which is slightly hazardous (Table 55.1).

On long-term exposure, benalaxyl causes liver steatosis and hematological changes in rats and atrophy of seminiferous tubules in dogs. In mice, increased mortality associated with amyloidosis has been observed. Reproductive abnormalities in rats include decreased body weight gain, increased liver weight of pups and delayed ossification of cranial bones. Minor skeletal deviations at maternally toxic levels have been reported in rabbits (JMPR, 2005). Metalaxyl is a 1:1 mixture of R-enantiomer and S-enantiomer. Technical-grade metalaxyl-M consists of

a minimum of 97% of the R-enantiomer and 3% of the S-enantiomer. The two compounds are used as fungicides and are severe irritants to rabbits. The dog is the most sensitive species, with the liver as the target organ. Both substances cause hepatocellular enlargement in rats, whereas dogs show changes in blood biochemical parameters indicative of hepatocellular damage (JMPR, 2002). Dichlofluanid and tolylfluanid have a fluorine atom substituted for one of the three chlorine atoms on the trichloromethylthio moiety of captan and folpet. Both compounds do not share a common mechanism of action with captan and folpet with regard to mouse duodenal tumors, principally because they do not induce these tumors. Flutolanil is slightly irritating to the eye. On long-term exposure, it leads to enlargement of the liver, decreased body weight and mild hematological

disturbances, with evidence of increased thyroid weight in rats and dogs. On long-term exposure to fenhexamid, the major target organ is the kidney in rats and mice and the hematopoietic system (increase in Heinz bodies) and adrenal gland in dogs. At higher doses, delayed ossification has been observed in rabbits but is not teratogenic (JMPR, 2005). Tolyfluanid is a skin sensitizer and can lead to sedation, decreased motility, disturbed behavior and dyspnea. After intraperitoneal injection, signs consistent with local irritation, altered liver enzyme activity, increased liver weight and histopathological changes that are indicative of liver toxicity in mice, rats and dogs have been reported. At higher doses, signs of renal toxicity and discoloration of bones and teeth, particularly the skull cap and incisors, have been observed. Alterations in thyroid hormone levels have also been observed in a number of studies in rats. The compound causes decreased pup viability at maternally toxic doses but is not teratogenic. These amides are neither genotoxic nor have any carcinogenic potential in animals (JMPR, 2002).

## Others

Several other antibiotic substances, thiocarbonates and cinnamic acid derivatives are used as fungicides. For

example, sodium tetrathiocarbonate, a thiocarbonate fungicide, is moderately toxic. The rat oral LD<sub>50</sub> is 631 mg/kg BW. It is a severe irritant to rabbit skin and a marked irritant to rabbit eyes. Another compound, cycloheximide, is extremely toxic, including development toxicity (Table 55.2), and has mutagenic potential. Dimethomorph has low oral toxicity in rats, is not an irritant to rabbit skin and is a minimal irritant to rabbit eyes. The acute oral LD<sub>50</sub> of fenpyroximate is 245 and 480 mg/kg BW in male and female rats, respectively. The compound may cause developmental toxicity in rats. Fludioxonil, a phenylpyrrole fungicide, and trifloxystrobin have low acute toxicity in rats. Fludioxonil is a slight eye irritant in rabbits, but it is neither a skin irritant in rabbits nor a skin sensitizer in guinea pigs. On long-term exposure, it causes liver necrosis, kidney nephropathy and mild anemia, and blue coloration of the urine and perineal fur. Reproductive toxicity indicates decreased pup weight gains in rats at parentally toxic doses. Trifloxystrobin is non-irritating but may be a skin sensitizer. Toxic symptoms are associated with liver toxicity, changes in kidney weight, atrophy of the pancreas and spleen abnormalities. Development toxicity indicates decreased body weight gain of pups accompanied by delayed eye opening at parentally toxic doses (JMPR, 2004).

## ENDOCRINE DISRUPTION

In both males and females, some fungicides affect reproduction through different mechanisms of action by endocrine disruption: exogenous agents interfere with normal reproduction and development processes. In males, normal reproductive function involves interaction of the hypothalamic–pituitary–testis axis and the thyroid gland. In females, increased concentrations of xenoestrogens may affect ovarian function through the disruption of feedback mechanisms in the hypothalamus–pituitary–gonadal axis (Flaws and Hirshfield, 1997; Bretveld *et al.*, 2006). Fungicides, like other chemicals, may disrupt all stages of hormonal function of the reproductive system. In females, during pregnancy, and to a greater extent during lactation, a portion of the maternal body burden of these chemicals is transferred to the offspring. Fungicides that are toxic to endocrine cells and that delete germ cells are beyond the scope of this chapter. However, it is well known that some fungicides affect male and female reproduction through different mechanisms of action by endocrine disruption. For example, fenarimol, prochloraz and chlorothalonil cause infertility in male and female rats through inhibition of CYP450 enzymes involved in steroid metabolism and alter sexual differentiation through antagonism of the androgen receptor(s) (Ankley *et al.*, 2005; Noriega *et al.*, 2005). The fungicide vinclozalin was shown to have endocrine-modulating effects in male offspring when rat dams were treated during the last one-third of gestation through postnatal day 3. The anogenital distance was reduced, and there were cleft phallus, hypospadias and other malformations in the offspring (Gray *et al.*, 1994). Procymidone has anti-androgenic properties. Long-term exposure of rats to procymidone had different effects on the pituitary–gonadal axis *in vivo* and on Leydig cell steroidogenesis *ex vivo*. The disruption of hormonal feedback could be due to its anti-androgenic action through activation of the endocrine axis, thereby causing hypergonadotropic activation of testicular steroidogenesis (Svechnikov *et al.*, 2005). From experimental studies, it has been concluded that fungicides can disturb the reproduction and development processes of both males and females through endocrine signals in organisms indirectly exposed during prenatal or early postnatal life. Such effects during fetal development may be permanent and irreversible. They may act through hormone receptors and enhance or diminish the activity normally controlled by endogenous hormones. According to one estimate, in 2003, eight fungicides (benomyl, hexachlorobenzene, mancozeb, maneb, metiram complex, tributyltin, zineb and ziram) were identified as potentially causing endocrine disruption in animals. Most of these were identified accidentally rather than as a result of an exhaustive screening process (Pocar *et al.*, 2003).

## TREATMENT

In some cases, there is no treatment, whereas in others supportive therapy as required by condition is indicated: (1) in the initial stages, use of emetics, gastric lavage, or activated charcoal may be helpful for removal of residual material from the GI tract; (2) oxygen should be provided immediately to meet oxygen demand; (3) body temperature should be lowered (use of cool baths, cool sponging, or placing the animal in the shade or in a cool, quiet room); (4) phenothiazine tranquilizers by the intramuscular route are advised to decrease exertion and stress and to facilitate handling of the animal; however, these should not be used to sedate or comatose the animal; (5) balanced electrolyte solution should be administered to prevent dehydration; and (6) the animal should be removed immediately from the exposure site. In the case of metallic poisoning, there is no satisfactory treatment of organomercurial toxicosis in farm or pet animals. Once developed, brain lesions are irreversible, and treatment in such cases is meaningless. Traditional chelators such as dimercaprol (BAL) or sodium thiosulfate have been recommended for many years but have little or no value due to their poor affinity for organomercury compounds (Gupta, 2010b).

## CONCLUSIONS AND FUTURE DIRECTIONS

Fungicides vary widely in chemical structure and thus in toxicity to livestock. The main hazard to livestock from fungicides is likely to arise from their use as dressings for the protection of stored grains, potatoes, etc. A number of livestock poisoning cases result from feeding of treated grains. Most available toxicity data are from laboratory animals; little information is available for farm animals and pets. In general, fungicides have low to moderate toxicity. However, several fungicides, such as alkylthiocarbamic acid (manganese, zinc and ammonium salts), halogenated substituted monocyclic aromatics (dinocap), carbamic acid derivatives (maneb and zineb metabolites and ethylenethiuram monosulfide), ferbam, mancozeb and maneb metabolites, HCB, benzimidazoles (benomyl and carbendazim), bis(tri-*n*-butyltin)oxide, chloroalkylthiocarboximides (captafol and folpet) and tridemorph are known to cause developmental toxicity and oncogenesis. More than 80% of all oncogenic risk from the use of pesticides derives from a few fungicides; only a small number of pesticide-related deaths from fungicides have been reported. Some fungicides are known to disrupt the endocrine system and may lead to reproductive and developmental

abnormalities. Based on teratogenicity, several fungicides including cycloheximide have been deregistered or banned in many countries but are still used in other, less regulated areas of the world. Other fungicides are undergoing re-evaluation because of changing regulatory policies; suspected toxicity, particularly as carcinogenic, mutagenic, or toxic to reproduction; and incomplete or outdated toxicity database.

## Anticoagulant rodenticides

Michael J. Murphy

### INTRODUCTION

The origin of oral anticoagulant therapy and anticoagulant rodenticides traces back to investigations of moldy sweet clover poisoning in the 1920s. This disease of cattle in Wisconsin was characterized by high mortality and internal bleeding. Investigations revealed that the diseased cattle had been fed moldy sweet clover hay.

An association between vitamin K and coagulopathies was made in the mid-1930s (Dam, 1935; Fieser *et al.*, 1939). Soon thereafter, Professor Link reported the discovery of dicoumarol in the moldy hay (Last, 2002). Naturally occurring coumarin in sweet clover hay is converted by fungi to dicoumarol. Dicoumarol was found to be the causative agent of the disease, so the elements needed for the disease were coumarin-containing plant material plus mold growth. Subsequently, a range of molecules were synthesized. Warfarin became the most popular (Duxbury and Poller, 2001). Warfarin takes its name, in part, from the Wisconsin Alumni Research Foundation. Warfarin and dicoumarol found application as both oral anticoagulants and rodenticides. Sweet clover requires the action of molds to form dicoumarol, whereas giant fennel does not.

Giant fennel, *Ferula communis*, grows in Mediterranean countries. It has a naturally occurring anticoagulant effect. An association between the plant and anticoagulation was first reported in the 1950s (Costa, 1950a,b; Carta, 1951). It was further investigated in Italy (Mazzetti and Cappelletti, 1957; Corticelli and Deiana, 1957; Corticelli *et al.*, 1957; Cannava, 1958) and then Israel (Shlosberg and Egyed, 1983). The anticoagulant activity of the plant in Morocco has been reviewed (Lamnaouer, 1999).

Five coumarins and 11 daucane derivatives have been isolated from *F. communis* (Arnoldi *et al.*, 2004). Previously identified chemicals include allohedycaryol (Zhabinskii, 1996), fercoperol (Miske *et al.*, 1986), and ferulenol.

The toxicity of ferulenol in rats, mice, and sheep has been reported. Ferulenol is a 4-hydroxycoumarin with the expected anticoagulation effects (Fraigui *et al.*, 2002). The single oral LD<sub>50</sub> of ferulenol in albino mice is 2100 mg/kg body weight (BW) (Fraigui *et al.*, 2002). This value is quite similar to oral LD<sub>50</sub> values of 1650 and 2000 mg/kg for rats and mice, respectively, obtained using fessoukh, the resinous gum of *Ferula* (Fraigui *et al.*, 2001). This supported results of prior studies in rats (Aragno *et al.*, 1988; Tagliapietra *et al.*, 1989).

Anticoagulation activity of the plant in sheep was reported in 1985 (Shlosberg and Egyed, 1985). Subsequently, ferulenol has been measured in the serum of sheep experimentally dosed with 600 g of powdered plant material (Tligui *et al.*, 1994). Ferulenol was detected 6 h after dosing and for approximately 12 h after cessation of dosing. The prothrombin time (PT) was elevated to six times normal approximately 70 h after the last dose and returned to normal by day 5 (Tligui and Ruth, 1994; Tligui *et al.*, 1994).

*Ferula* has also been examined for chemotherapy (Poli *et al.*, 2005), antimycobacterial (Appendino *et al.*, 2004; Mossa *et al.*, 2004), and microtubule effects (Bocca *et al.*, 2002) and for testicular and epididymal changes in rams (Gil *et al.*, 2002), much like warfarin and other oral anticoagulants have been examined. It is found in Morocco (Fraigui *et al.*, 2001), Israel (Shlosberg and Egyed, 1983), and Italy (Tagliapietra *et al.*, 1989).

The term oral anticoagulants normally refers to these chemicals when used therapeutically. The oral anticoagulants are briefly discussed before a detailed discussion of the application of the dicoumarol progeny as anticoagulant rodenticides is presented.

Warfarin and its congeners are still used as therapeutic agents. Oral anticoagulants available therapeutically in Europe include warfarin, phenprocoumon, and nicoumalone, which is also called acenocoumarol (Shetty *et al.*, 1993). Oral anticoagulants are used therapeutically to reduce thromboembolic events. Warfarin examples include a reduction in catheter-related thrombosis (Guidry *et al.*, 1991; Magagnoli *et al.*, 2006); early venous thrombosis after operations (Calnan and Allenby, 1975; Pan *et al.*, 2005), including hip surgery; atrial fibrillation (Middlekauff *et al.*, 1995; Reiffel, 2000); and myocardial infarction (Asperger and Jursic, 1970). Dicoumarol is also used in the therapy of thrombotic occlusion of intracoronary stents (Alonso Martin *et al.*, 1997), prosthetic valves (Dalla, 1994), and other types of venous thromboses (Piovela *et al.*, 1995; Ferlito, 1996) or thrombophlebitis (Byrne, 1970; Creutzig, 1993).

Warfarin may also reduce the recurrence of malignant melanoma (Thornes *et al.*, 1994) or small cell lung cancer (Aisner *et al.*, 1992). This anti-metastatic activity may be associated with the distribution of metastatic cells on thrombi (McNiel and Morgan, 1984; Smith *et al.*, 1988).

Low-dose warfarin therapy has been adopted in the United States, Europe, and by the World Health Organization (Duxbury and Poller, 2001). The international normalized ratio (INR) is used to measure anticoagulation (Duxbury and Poller, 2001).

Oral anticoagulants have been used for decades, and a number of adverse events have been recognized. Most are related to drug interactions (Dayton and Perel, 1971). Although controversy exists regarding whether acetaminophen induces an adverse effect on warfarinized patients in therapeutic doses (Toes *et al.*, 2005), the acetaminophen metabolite NAPQI (*N*-acetyl-*para*-benzoquinoneimine) seems to interfere with vitamin K-dependent  $\gamma$ -carboxylase. Such interference may lead to potentiation of the anticoagulant effect of warfarin (Thijssen *et al.*, 2004). COX-2 inhibitors may interfere with control of warfarin anticoagulation in elderly patients (Savage, 2005), and rifampin may interfere with warfarin metabolism due to induction of P450 activity (Strayhorn *et al.*, 1997; Finch *et al.*, 2002). Inconsistent anticoagulation has been recognized in generic versus prescription warfarin (Burns, 1999), and a single case of hemothorax with eosinophilia has been reported in a warfarin overdose (Nasilowski and Krenke, 2002).

Complementary or alternative medical therapies may also interfere with warfarin metabolism (Tumova, 2000; Wood *et al.*, 2003). For example, passionflower,

hydroalcoholic extracts, juniper, and verbena contain vitamin K<sub>1</sub>, so they can lessen the anticoagulation effect of warfarin therapy (Argento *et al.*, 2000). On the other hand, genoderma, japonicum, papaw, *Salvia miltiorrhiza*, ginseng, devil's claw, garlic, quinine, ginkgo, ginger, red clover, and horse chestnut may reinforce the anticoagulant effect of warfarin by various mechanisms (Argento *et al.*, 2000).

A "coumarin-induced hepatitis" has been reported in warfarinized patients (Rehnqvist, 1978; Bint and Burt, 1980; Tanaka *et al.*, 1985; Hohler *et al.*, 1994; Matsukawa *et al.*, 1994; Ehrenforth *et al.*, 1999; Bamanikar and Hiremath, 2002; Biagini *et al.*, 2006). Liver damage has also been reported in a brushtail possum (*Trichosurus vulpecula*) dosed with the anticoagulant rodenticide pindone (Jolly *et al.*, 1994). Pindone has been associated with an increased frequency of sex chromosome loss in *Drosophila melanogaster* (Santoro *et al.*, 1993). The remainder of the chapter is devoted to the application of the chemical progeny of dicoumarol to pest control.

## BACKGROUND

In the 1940s, a small British pharmaceutical company suggested that dicoumarol might have rodenticidal properties. Trials carried out by Armour and Barnett (1950) confirmed the idea and started the era of anticoagulant rodenticides. Warfarin was the first anticoagulant rodenticide introduced into the market soon after World War II and became widely used in many countries. Other anticoagulant compounds with potency similar to that of warfarin were also synthesized. These early anticoagulant rodenticides are often called first-generation anticoagulant rodenticides. These first-generation compounds generally have moderate toxicity, with acute LD<sub>50</sub> values ranging from 10 to 50 mg/kg BW. The first-generation compounds often needed continuous bait exposure for rodent control.

Many rodent species developed a resistance to warfarin presumably due to continued exposure and widespread use (Jackson *et al.*, 1975). Consequently, new chemical structures were synthesized and used as anticoagulant rodenticides. These newer compounds are generally more toxic than warfarin, with acute LD<sub>50</sub>s of 0.2–3.9 mg/kg BW. For example, a bait concentration of only 50 ppm of brodifacoum is adequate to give control in a single feeding for most rodents and non-commensal species (Matolesy *et al.*, 1988). These newer compounds are called second-generation anticoagulant rodenticides, and they are often referred to as "super-warfarins" in the contemporary medical literature

TABLE 56.1 Oral LD<sub>50</sub> values (mg/kg body weight) of some anticoagulant rodenticides

Animal	LD <sub>50</sub> (mg/kg body weight)		
	Bromadiolone	Brodifacoum	Difenacoum
Rat (acute)	0.65	0.27	1.8
Rat (chronic)	(0.06–0.14) × 5	(0.05–0.08) × 5	0.15 × 5
Mouse	0.99	0.4	0.8
Rabbit	1.0	0.2	2.0
Pig	3.0	10.0	80.0
Dog	10.0	3.5	50.0
Cat	25.0	25.0	100.0
Chicken	5.0	10.0–20.0	50.0
Guinea pig	2.8	–	–
Opossum	–	0.17	–
Sheep	–	10.0	100.0

(Chong *et al.*, 1986; Greeff *et al.*, 1987; Swigar *et al.*, 1990; Wallace *et al.*, 1990; Routh *et al.*, 1991; Wilton, 1991; Exner *et al.*, 1992; Rauch *et al.*, 1994; Hui *et al.*, 1996; Tecimer and Yam, 1997; Chua and Friedenber, 1998; Gallo, 1998; Pavlu *et al.*, 2005; Sharma and Bentley, 2005; Dolin *et al.*, 2006).

Anticoagulant rodenticides are also categorized based on chemical structures. The chemical structures of the currently marketed products are classified into two chemical classes: hydroxycoumarins and indanediones.

Hydroxycoumarins have a 4-hydroxycoumarin ring with different side chain substituents at the 3-position. Commonly used anticoagulant rodenticides in this group are bromadiolone, brodifacoum, coumatetralyl, coumatetralyl, difenacoum, and warfarin.

Indanediones have a 1,3-indanedione structure with different side chain substituents at the 2-position. The most common anticoagulant rodenticides in this group are chlorophacinone and diphacinone. Each of these compounds are briefly summarized later.

Several representative chemicals are described next. A number of other chemicals have also been developed.

## Hydroxycoumarins

### Bromadiolone

Bromadiolone (3-(3-(4'-bromobiphenyl-4-yl)-3-hydroxy-1-phenyl propyl)-4-hydroxycoumarin) was synthesized and

marketed by the French company Liphia S.A. during the mid-1970s. It is used widely for control of commensal and field rodents in many countries. Technical-grade bromadiolone is 97% pure. It is a yellowish powder and stable up to 2000°C (Chalermchaikit *et al.*, 1993). It is very soluble in dimethylformamide (730 g/L), less soluble in ethyl acetate (25 g/L) and ethanol (8.2 g/L), and sparingly soluble in water (0.019 g/L). Bromadiolone is considered more palatable to rodents than most other anticoagulants. Its concentration in baits is usually 50 ppm (Chalermchaikit *et al.*, 1993). Although bromadiolone is considered a second-generation anticoagulant rodenticide, some resistance problems have been reported with *Rattus norvegicus* and *Mus musculus* in the United Kingdom and Denmark (Lund, 1971; Rowe *et al.*, 1981).

### Brodifacoum

Brodifacoum (3-(3-(4'-bromobiphenyl-4-yl)-1,2,3,4-tetrahydronaphth-1-yl)-4-hydroxycoumarin) is one of the newer and more potent second-generation anticoagulant rodenticides. It was introduced in 1977 by Sorex Ltd. of London and then developed by the Imperial Chemicals Incorporated (ICI) Plant Protection Division (Chalermchaikit *et al.*, 1993).

Pure brodifacoum is an off-white to fawn-colored powder with a solubility of 6–20 g/L in acetone, 3 g/L in chloroform, 0.6–6 g/L in benzene, and less than 10 mg/L in water. It is very stable in the environment, with no loss after 30 days of exposure to direct sunlight (Chalermchaikit *et al.*, 1993).

Brodifacoum has been marketed in several countries for the control of a wide range of rodent pest species. It is available as a 0.005% pellet for rat and house mice controls, a smaller 0.001% pellet for field rodent control, and as 29-g wax blocks for sewer rat control. It is the only anticoagulant rodenticide to produce 100% mortality in most rodent species after only a 24-h dose (Chalermchaikit *et al.*, 1993). Brodifacoum was effective against warfarin-resistant rats and mice in 1984, but the possibility of resistance has been raised (Lund, 1984).

There is variation in the susceptibility of species to brodifacoum. The average pig, sheep, or chicken must consume considerable quantities of prepared bait to be endangered. However, dogs are susceptible and are

commonly exposed to potentially toxic quantities of brodifacoum (Chalermchaikit *et al.*, 1993).

#### Coumatetralyl

Coumatetralyl (3-(alpha-tetralyl)-4-hydroxycoumarin) was introduced by Bayer AG with the trademark name of Racumin. It has been used for commensal control in many countries. It is formulated as a dry bait (0.0375%), a liquid bait of its sodium salt, and a 0.75% tracking dust (Chalermchaikit *et al.*, 1993).

Pure coumatetralyl is a colorless powder that is stable at temperatures below 150°C. Its solubility is 20–50 g/L in propan-2-ol, 50–100 g/L in methylene dichloride, and 4 mg/L in water. The acute and chronic LD<sub>50</sub>s to *R. norvegicus* are 16.5 and 0.3 mg/kg for five consecutive doses, respectively. Chickens are quite resistant to coumatetralyl, with a chronic LD<sub>50</sub> of 50 mg/kg for eight consecutive doses. Signs did not appear in fish until the concentration of coumatetralyl reached 1000 mg/L in water (Chalermchaikit *et al.*, 1993).

Despite its low toxicity, it is reported to be slightly more effective than warfarin against *R. norvegicus*, apparently due to higher palatability. Coumatetralyl was introduced after the detection of warfarin-resistant rat populations and showed considerable success for a number of years, but resistant pests have been reported in the United Kingdom and Denmark (Rowe and Redfern, 1968; Lund, 1988).

#### Coumafuryl

Coumafuryl (3-(alpha-acetyl-2-furyl)-4-hydroxycoumarin) is a German anticoagulant, introduced in 1952, and is used at 0.025–0.05% in baits. Its toxicity is considered equal to that of warfarin for *R. norvegicus* but slightly less efficient against *M. musculus*. The chronic LD<sub>50</sub> in *R. norvegicus* is 1.4 mg/kg for five repeated doses. Cats and dogs seem to be almost as susceptible as rats, with dogs being killed by 2 mg/kg for five repeated doses and cats by 10 mg/kg for four repeated doses (Chalermchaikit *et al.*, 1993).

#### Difenacoum

Difenacoum (3-(3-(p-diphenyl)-1,2,3,4-hydronaphth-1-yl)-4-hydroxycoumarin) was synthesized in the United Kingdom and marketed in 1975 by Sorex Ltd. under the trademark Neosorexa and by ICI Plant Protection Division under the trademark Ratak as a 0.005% pelleted bait and as a wax block. Pure difenacoum is an off-white powder with a solubility of greater than 50 g/L in acetone, 600 mg/L in benzene, and less than 10 mg/L in water. It is more toxic than warfarin, but it is less palatable. Difenacoum is still effective against many populations of warfarin-resistant rats (Desideri *et al.*, 1979), but resistance may be developing in the United Kingdom (Greaves *et al.*, 1982).

#### Warfarin

Warfarin (3-(alpha-acetylbenzyl)-4-hydroxycoumarin) was the first anticoagulant rodenticide, introduced soon after World War II after development by the Wisconsin Alumni Research Foundation. Warfarin is still used widely, especially for the control of *R. norvegicus* in areas where resistance has not developed. In its racemic form, warfarin is colorless and crystalline, insoluble in water, but readily soluble in acetone, dioxane, and moderately soluble in alcohols. Warfarin is formulated as dry bait (0.005–0.05%) as well as a liquid bait, based on the sodium salt, and a tracking dust (0.5–1.0%). It is generally applied as the S-isomer, which has a toxicity 10 times greater than that of the R-isomer. The acute and chronic LD<sub>50</sub>s for *R. norvegicus* are approximately 10–12 mg/kg and 0.75 mg/kg for five repeated doses, respectively (Colvin and Wang, 1974).

Warfarin is sometimes combined with an antibacterial agent, sulfaquinoxaline, to reduce the bacterial production of vitamin K in the rat intestine, but the effectiveness of this combination has not been proven. Warfarin is considered one of the safest anticoagulants with regard to domestic and other non-target animals. Serious resistance problems have been reported in Europe. It has been evaluated against sewer rats in London (Channon *et al.*, 2000).

## Indanedione group

### Chlorophacinone

Chlorophacinone (2-(alpha-(4-chlorophenyl)-1-phenylacetyl)-1,3-indandione) was first introduced during the mid-1960s by Liphia S.A. of France at concentrations of 0.05% in baits and 0.2% in tracking dust. Pure chlorophacinone is a yellow crystalline solid that is very soluble in acetone, ethanol, and ethyl acetate but is sparingly soluble in water. It is quite stable, and it is resistant to weathering. Chlorophacinone does not induce "bait shyness" and is compatible with cereals, fruits, roots, and other potential bait substances. Its acute LD<sub>50</sub> in *R. norvegicus* is approximately 20.5 mg/kg, which is less toxic than warfarin, but it has a stronger initial effect on rats and mice. For control of house mice populations, a prolonged feeding period is needed. Chlorophacinone is not effective against warfarin-resistant rodents (Chalermchaikit *et al.*, 1993).

### Diphacinone

Diphacinone (2-diphenylacetyl-1,3-indandione) is an old anticoagulant rodenticide, introduced by Vesicol Chemical Corp. and the Upjohn Company. It has been produced and used primarily in the United States as a 0.005% dry or liquid bait. Pure diphacinone is a yellow powder that is very soluble in chloroform (204 g/kg), toluene (73 g/kg), xylene (50 g/kg), and acetone (29 g/kg) but sparingly soluble in water (0.30 g/L). It will decompose in water due to sunlight. The acute LD<sub>50</sub>s in

*R. norvegicus* are 22.7 mg/kg in females and 43.3 mg/kg in males. It is more toxic than warfarin to rats, mice, and dogs, but its palatability is somewhat lower. Diphacinone is not effective against warfarin-resistant rodents (Chalermchaikit *et al.*, 1993).

The anticoagulant rodenticides are marketed to have efficacy against a number of target pest species. These species are listed next by chemical compounds.

## TARGET SPECIES

### Brodifacoum

One day of feeding on a 0.005% brodifacoum or difenacoum bait was successful in controlling the lesser bandicoot rat (*Bandicota bengalensis*) in Burma (Brooks *et al.*, 1980). Within 3 days, a 0.005% brodifacoum bait gave complete control of golden hamsters (*Mesocricetus auratus*) resistant to 0.005% warfarin and difenacoum (Bradfield and Gill, 1984). A 20-ppm brodifacoum bait gave virtually complete control of Norway rats (*R. norvegicus*) in 21–73 days after other treatments had failed (Greaves *et al.*, 1982). At a 0.005% bait concentration, brodifacoum was more effective at 8 days in controlling *Meriones shawi* than warfarin at 0.025%, coumatetralyl at 0.0375%, difenacoum at 0.005%, and bromadiolone at 0.005% (Gill and Redfern, 1983). The efficacy of brodifacoum has also been shown for *Tatera indica* (Rehman and Ahmad, 1983); *Tatera indica*, *Nesokia indica*, and *Bandicota bengalensis* (Greaves and Rehman, 1977); the field mouse *Mus booduga* Gray (Balasubramanyam *et al.*, 1984); *Rattus rattus* and *Bandicota bengalensis* (Deobhankar, 1985); eight rodent species (Lund, 1981, 1988); the Egyptian spiny mouse (*Acomys cahirinus*) (Mahmoud and Redfern, 1981); and nonresistant (Mosterd and Thijssen, 1991) and warfarin-resistant rats (Rennison and Dubock, 1978). A number of early studies were conducted under the designation WBA 8119 (Rowe and Bradfield, 1976; Rowe *et al.*, 1978). Several different rodenticides have been tested for efficacy against rodent in cucumber (*Cucumis sativus*) plantings (Sabhlok *et al.*, 1997). Brodifacoum has been used to control brown necked ravens (*Corvus ruficollis*) in the Suez Canal region (El-Bahrawy *et al.*, 2007).

### Bromadiolone

Bromadiolone has been effective against warfarin-resistant rats and mice (Redfern and Gill, 1980). It is effective against the Norway rat (*Rattus norvegicus*) (Richards, 1981; Kamil, 1987). Bromadiolone residues have been examined in tissues of *Arvicola terrestris* (Giraudoux *et al.*, 2006) and coypu (*Myocastor coypus*) (Jeantet *et al.*, 1991) after field use. Its effects on the breeding performance of house mice have also been investigated (Twigg and Kay, 1995).

## Chlorophacinone

The efficacy of chlorophacinone against mice, voles, and squirrels has been established. At a 25-ppm bait concentration, chlorophacinone is more effective than coumachlor in controlling common mice (*M. musculus*) in Egypt (Mesban *et al.*, 2003). It can control common voles (*Microtus arvalis*) (Nikodemusz *et al.*, 1981), palm squirrels (*Funambulus pennanti*) (Mathur and Prakash, 1980), and house mice (*M. musculus*) (Lund, 1971).

## Coumafuryl

Coumafuryl is more effective on *R. rattus*, *R. norvegicus*, and *B. bengalensis* than are fumarin and warfarin when used in liquid form (Renapurkar, 1982). It was effective in controlling the cotton rat (*Sigmodon hispidus*) at concentrations used to control *R. rattus* and *R. norvegicus* (Gill and Redfern, 1980) and *Mastomys natalensis* (Gill and Redfern, 1979).

## Coumatetralyl

Median survival time was 4.7 and 11.2 days in *B. bengalensis* and *R. rattus* exposed to 0.0375% coumatetralyl bait (Chopra and Parshad, 1985).

## Diphacinone

Diphacinone has been shown to control rats (Elias and Johns, 1981), vampire bats (Burns and Bullard, 1979, 1980; Thornton, 1980), *B. bengalensis* (Brooks *et al.*, 1980), and coyotes (Szuber and Diechtiar, 1968; Sterner, 1979).

## Difenacoum

Fifty percent of male mice exposed to 0.5mg difenacoum/kg BW died within 9 days, whereas no female mice died (Winn *et al.*, 1989). Norway rats (*R. norvegicus*) fed 25ppm difenacoum bait for 5, 10, or 20 days had whole carcass residues of 0.52–0.74mg/kg BW, with the higher amount being present after the longer feeding period (Rennison and Hadler, 1975; Redfern and Gill, 1980; Atterby *et al.*, 2005). A symptom-dependent taste aversion of the brown rat (*R. norvegicus*) has been reported because the taste aversion is only present when signs are present in the animal (Smith *et al.*, 1994).

## Flocoumafen

Flocoumafen has been demonstrated to control *R. rattus*, *B. bengalensis* (Parshad and Chopra, 1986), *R. norvegicus*

(Buckle, 1986), and the house mouse (*M. musculus*) (Rowe *et al.*, 1985a,b). Flocoumafen gave a quicker and equally effective kill of 68 mice (*M. musculus*) exposed to a 0.005% oatmeal bait compared to difenacoum, brodifacoum, and brodifacoum at the same bait concentrations (Rowe *et al.*, 1985a,b). Nonbiliary intestinal elimination of flocoumafen has been reported in rats (Huckle *et al.*, 1989a,b), and metabolic and toxicological studies have been reported (Veenstra *et al.*, 1991). Accumulation of flocoumafen in rats after repeated exposure has been examined (Huckle *et al.*, 1988).

## Flupropadine

Flupropadine is nearly as effective as calciferol/warfarin in control of the house mouse (*M. musculus*) (Rowe *et al.*, 1985a,b).

## Warfarin

The efficacy of warfarin has been evaluated against squirrels (Chambers and Chambers, 1983) and a host of other species.

## NON-TARGET SPECIES

Unfortunately, non-target species may also be exposed to anticoagulant rodenticides, which are a potential hazard to all species of mammals and birds. The environmental, avian, and wildlife species so exposed are summarized briefly, followed by a discussion of non-target exposure in humans and domestic animals.

## Environmental

Anticoagulant rodenticides may be detected in water, soil, and invertebrates. A method of detecting warfarin in water has been reported (Badia and Diaz-Garcia, 1999), perhaps because anticoagulant rodenticides are used in rice paddies (Baskaran *et al.*, 1995), and accidental discharges of brodifacoum bait may occur in freshwater or marine environments (Primus *et al.*, 2005). The toxicity of anticoagulant rodenticides in soil may be related to the portion not bound to humic acid. Testing for the halogenated biphenyl side chain has been suggested as a way to determine soil exposure to rodenticides (Townsend *et al.*, 1995).

Diphacinone has been detected in snails and slugs in Hawaii. It ranged from 0.8 to 2.5ppm in *Oxychilus* species snails, from 1.3 to 4.0 in *Deroceras laeve* slugs, and up to 1.8ppm in *Limax maximus* slugs (Primus *et al.*, 2006).

## Wildlife

Anticoagulant rodenticides have been detected in polecats and mink in the wild. Difenacoum and bromadiolone were detected in 35% of male (13 of 37) and 38% of female (5 of 13) polecats (*Mustela putorius*) collected in England and Wales in areas where the baits had been used (Shore *et al.*, 2003). Spatial and temporal residues in polecats in Britain have also been reported (Shore *et al.*, 2003). A previous study found difenacoum in 7 of 24 livers (Shore *et al.*, 1996). In France, populations of the free-ranging European mink (*Mustela lutreola*) have declined. Investigators found bromadiolone and chlorophacinone residues in the livers of four species of free-ranging mink and raised the question of the risk to European mink from anticoagulant rodenticides (Fournier-Chambrillon *et al.*, 2004). There are also risks of brodifacoum exposure in non-target birds and animals (Eason *et al.*, 2002). Secondary poisoning of fox after broadcast of anticoagulant rodenticides for voles has been proposed (Raoul *et al.*, 2003). Bromadiolone toxicosis of coypu has also been reported (Morin *et al.*, 1990).

## Avian

Anticoagulant rodenticide toxicosis of birds has been reported throughout the United States and in Australia (Reece *et al.*, 1985). Brodifacoum and difenacoum residues have been detected in a number of non-target avian species. Offspring of turkey vultures (*Cathartes aura*) died after being fed brodifacoum-poisoned mice in a zoo setting. Similar residues have been detected in other carnivorous birds, including *Dacelo novae-guinae* and *Tockus deckeni*.

Ten percent of barn owls collected in England had detectable residues of difenacoum or brodifacoum in their livers. Liver concentrations of difenacoum and brodifacoum ranged from 5 to 106 ng/g and 19 to 515 ng/g, respectively. Mice were fed difenacoum and brodifacoum baits and died within 2–11 days. Poisoned mice were fed to barn owls for 1, 3, or 6 days. All six owls fed difenacoum mice survived, and coagulation times returned to normal in 5–23 days. Four of six owls fed brodifacoum-dosed mice died 6–17 days after feeding. Dead owls had 630–1250 ng/g brodifacoum in their livers (Newton *et al.*, 1990). A white-winged wood duck was treated for brodifacoum toxicity (James *et al.*, 1998), and secondary poisoning of stone martens (*Martes foina*) fed bromadiolone-poisoned mice has been suspected (Lund and Rasmussen, 1986).

Brodifacoum has also been implicated in poisoning of non-target wildlife in 80% of 55 animals investigated in the New York area. Diphacinone, bromadiolone, chlorophacinone, and coumatetralyl were also implicated. Exposure of raptors including great-horned owls (*Bubo virginianus*) and

red-tailed hawks (*Buteo jamaicensis*) constituted half the cases, with gray squirrels (*Scirurus carolinensis*), raccoons (*Procyon lotor*), and white-tailed deer (*Odocoileus virginianus*) constituting the others (Stone *et al.*, 1999).

A compilation of 164 stringiformes collected in western Canada between 1988 and 2003 showed that 70% had residues of at least one rodenticide, and of these, 41% had more than one. Barred owls (*Strix varia*) were most frequently exposed (92%), with the liver concentration of brodifacoum ranging from 0.001 to 0.927 mg/kg and that of bromadiolone ranging from 0.002 to 1.012 mg/kg (Albert *et al.*, 2010).

Broadcast diphacinone has also been implicated in avian toxicoses. Poouli is an endangered avian species in Hawaii. The probability of mortality for adult and juvenile Poouli after a 5-day exposure to broadcast diphacinone has been determined to be 3 and 8%, respectively. Diphacinone residues in snails apparently increase the risk of mortality in juvenile birds (Johnston *et al.*, 2005).

Diphacinone, dicoumarol, and pival have all been shown to increase PT in chicks (Charles *et al.*, 1966). Bromadiolone was detected both in fox (*Vulpes vulpes*) and in buzzards (*Buteo buteo*) in France (Berny *et al.*, 1997).

Chlorophacinone has also been examined. A no-observed-effect concentration of chlorophacinone in feed is 1 mg chlorophacinone/kg feed in Japanese quail (*Coturnix japonica*) (Riedel *et al.*, 1990). Emaciated California quail (*Callopepla californica*) were found to have impacted crops due to parafinized chlorophacinone pellets attributed to the paraffin because PT times were normal (Blus *et al.*, 1985). Chlorophacinone has also been studied in captive kestrels (Radvanyi *et al.*, 1988). A 100% mortality occurred in 1-week-old chicks fed coumestral in wood-straw mats (Munger *et al.*, 1993).

## MECHANISM OF ACTION

The mechanism of action of all anticoagulant rodenticides is similar to that of warfarin – that is, inhibition of vitamin K<sub>1</sub> epoxide reductase (Park *et al.*, 1979; Leck and Park, 1981; Breckenridge *et al.*, 1985). In the coagulation cascade, the clotting factors II, VII, IX, and X must bind calcium ions to be active in clot formation. The Ca<sup>2+</sup> binding ability requires converting glutamyl residues on these clotting factors to  $\gamma$ -carboxyl glutamyl residues by the process of carboxylation. Carboxylation uses vitamin K<sub>1</sub> hydroquinone as a cofactor. This vitamin K-dependent carboxylase reaction converts vitamin K<sub>1</sub> hydroquinone to its epoxide form, vitamin K<sub>1</sub> 2,3-epoxide. In the normal cycle, vitamin K<sub>1</sub> 2,3-epoxide is reduced to the original vitamin K<sub>1</sub> (phyloquinone) by enzyme epoxide reductase and is thus

recycled. Anticoagulant rodenticides produce their effect by interfering with the enzyme vitamin K<sub>1</sub> epoxide reductase, resulting in the depletion of vitamin K<sub>1</sub> and subsequently impairing the synthesis of normal clotting factors II, VII, IX, and X (Craciun *et al.*, 1997, 1998). Clinical coagulopathy soon follows the depletion of vitamin K<sub>1</sub> in the liver. Because these clotting factors in the dog have plasma half-lives of 41, 6.2, 13.9, and 16.5 h, respectively, a lag time of 3–5 days is commonly observed between ingestion of a bait and the onset of clinical signs (Jackson and Suttie, 1977; Suttie, 1986; Murphy and Gerken, 1989). The interrelationship of vitamin K, prothrombin, and  $\gamma$ -carboxyglutamic acid is reviewed in Stenflo (1978). The interaction of warfarin and vitamin K is reviewed in Suttie (1990).

## Biochemistry

Microsomal vitamin K-dependent carboxylase, vitamin K epoxidase, vitamin K<sub>1</sub> epoxide reductase, and cytosolic vitamin K reductase (DT-diaphorase; EC 1.6.99.2) are involved in vitamin K reduction (Hildebrandt and Suttie, 1982). The physiologically important site of action of the anticoagulant rodenticides is vitamin K<sub>1</sub> epoxide reductase (Hildebrandt and Suttie, 1982). Anticoagulant rodenticides act by inhibiting vitamin K<sub>1</sub> 2,3-epoxide reductase and consequently the synthesis of clotting factors II, VII, IX, and X. S-warfarin and difenacoum are more potent in complete inhibition of clotting factor synthesis than are racemic warfarin, R-warfarin, or brodifacoum (Breckenridge *et al.*, 1985).

The greater potency and duration of action of the long-acting or superwarfarins have been attributed to (1) a greater affinity for vitamin K<sub>1</sub> 2,3-epoxide reductase, (2) the ability to inhibit the vitamin K<sub>1</sub> epoxide cycle at more than one point, (3) hepatic accumulation, and (4) unusually long half-lives due to lipid solubility and enterohepatic circulation (Watt *et al.*, 2005). The two diastereomers of brodifacoum may have different conformational alignment with vitamin K epoxide reductase (Cort and Cho, 2009).

Rat liver has two pathways for vitamin K reduction. One is responsible for the therapeutic effect of vitamin K<sub>1</sub> therapy. This pathway is DT-diaphorase and a microsomal dehydrogenase that has 3.6-fold higher activity with NADH than with NADPH. It is not a cytochrome P450 or cytochrome b5 reductase (Wallin, 1986). Although dicoumarol, warfarin, and diphenadione inhibit NAD(P)H in rat liver *in vitro*, only dicoumarol inhibited the enzyme in rats dosed *in vivo* (Schor *et al.*, 1983).

Pathway I is inactive in warfarin and difenacoum intoxicated rats. Vitamin K<sub>1</sub> epoxide reductase was also inactive, so this may be part of pathway I *in vivo*. Pathway II mediates the therapeutic effect of vitamin K<sub>1</sub> and resulting carboxylation *in vitro* (Wallin, 1986).

Vitamin K and vitamin K<sub>1</sub> epoxide can be measured in serum (Bjornsson, 1978; Bjornsson *et al.*, 1979; Donnahey *et al.*, 1979) and tissue. A number of vitamin K detection methods have been reported (Williams *et al.*, 1972; Haroon *et al.*, 1980, 1986, 1987; Haroon and Hauschka, 1983; Hart *et al.*, 1984), including detection in human plasma (Langenberg and Tjaden, 1984) and serum (Lefevre *et al.*, 1979) using high-performance liquid chromatography (HPLC) with electrochemical detection (Takani and Suttie, 1983) or fluorimetric detection in liver (Usui *et al.*, 1989). The mode of action of vitamin K has been reviewed (Olson, 1966).

Because anticoagulant rodenticides inhibit the vitamin K<sub>1</sub> reductase reaction (Pelz *et al.*, 2005), vitamin K<sub>1</sub> epoxide is elevated and vitamin K<sub>1</sub> is reduced. For example, diphenadione- (Mount and Kass, 1989) and warfarin-exposed dogs (Carlisle and Blaschke, 1981) have elevated vitamin K<sub>1</sub> epoxide after subcutaneous vitamin K<sub>1</sub> administration.

Also, vitamin K<sub>1</sub> concentrations are low or nondetectable in rats 24 h after exposure to difenacoum (Winn *et al.*, 1987). Measurement of the epoxide in serum has been proposed as a method to detect surreptitious exposure (Bechtold and Jahnchen, 1979; Bechtold *et al.*, 1983). The disposition of vitamin K in anticoagulant rodenticide poisoning was examined by Park *et al.* (1984).

## Resistance

Resistance to anticoagulant rodenticides is largely transmitted as an autosomal dominant trait. Initially, investigators postulated that a genetic mutation in resistant rodents produced an enzyme epoxide reductase with a reduced binding affinity for warfarin and similar anticoagulants that resulted in resistance to warfarin (Bell and Caldwell, 1973; Zimmerman and Matschiner, 1974; Hadler and Shadbolt, 1975; Misenheimer *et al.*, 1994). This theory seems to have been borne out.

Eight different mutations in the vitamin K reductase reaction have been identified in laboratory strains of brown rats and house mice and in wild-caught brown rats. Five mutations are of only two amino acids. Resistance to warfarin is largely influenced by mutations at Tyr139 (Pelz *et al.*, 2005). The genomic assignment of the warfarin-resistant locus (Kohn and Pelz, 1999) and a gene anchored map of the rat warfarin-resistant locus (Kohn and Pelz, 2000) have been reported. These followed reports of the biochemical basis of warfarin and bromadiolone resistance in house mice (Misenheimer *et al.*, 1994). However, warfarin-resistant rats are not resistant to coumatetralyl, so there may be more than one mechanism of resistance (Bell *et al.*, 1976).

Feeding of difenacoum and menadione (vitamin K<sub>3</sub>) for 4 days is used as a test to determine the degree

of resistance of laboratory Norway rats (*R. norvegicus*) and wild rats to difenacoum (Gill *et al.*, 1993). Chemical differences of the side chains at the 3-position of the second-generation 4-hydroxycoumarins may provide a point of attachment to a lipophilic site on the epoxide reductase enzyme, where warfarin and other first-generation rodenticides do not bind strongly (Hadler and Shadbolt, 1975). This increased binding increases their toxicity and may reduce the development of resistance in rodents.

An absolute requirement for vitamin K<sub>1</sub> in Danish Norway rats (*R. norvegicus*) (Markussen *et al.*, 2003) and others resistant to warfarin remains is another theory (Trivedi *et al.*, 1988). Amino acid substitutions of the vitamin K epoxide reductase complex subunit 1 and increased expression of P450 (CYP) have been postulated (Ishizuka *et al.*, 2008).

## Antioxidant

The anticoagulant rodenticides and oral anticoagulants are also of interest in cancer research. In part, because catalyzing obligatory two-electron reductions of quinones to hydroquinones, NAD(P)H: quinone reductase (QR1) protects cells against the deleterious effects of redox cycling of quinones and their ability to deplete glutathione and produce neoplasia (Dinkova and Talalay, 2000). DT-diaphorase and coenzyme Q appear to have antioxidant and pro-oxidant functions in quinone metabolism (Beyer, 1994; Cadenas, 1995).

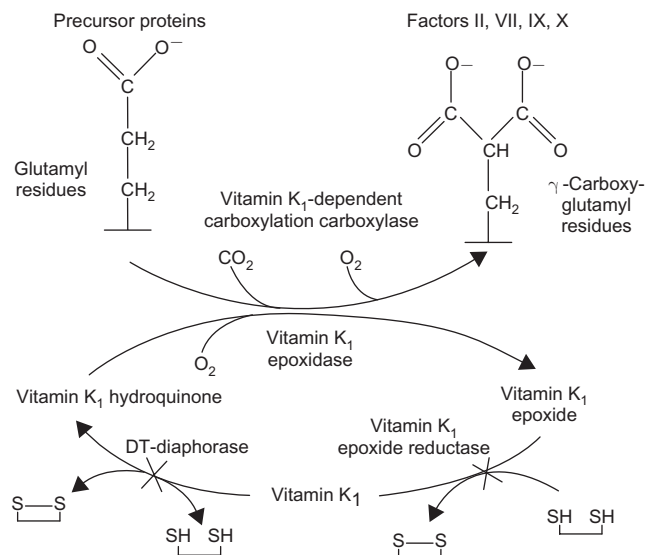

## Metabolism

Warfarin is metabolized by CYP 2C9 and 2C19 in humans (Goldstein, 2001; Brandon *et al.*, 2005). The CYP 2C9 enzyme has several inherited polymorphisms (Kirchheiner and Brockmoller, 2005). Chlorophacinone elimination may be enhanced by phenobarbital administration (Burocoa *et al.*, 1989; Lagrange *et al.*, 1999), perhaps due to CYP induction. The effect of phenobarbitone on vitamin K<sub>1</sub> metabolism (Wilson and Park, 1984) can be compared to that of the rabbit (Winn *et al.*, 1988).

# TOXICOKINETICS

## Bioavailability

Most anticoagulant rodenticide toxicoses occur after oral exposure. However, a diphacinone-induced coagulopathy has been reported after dermal exposure to a liquid preparation (Spiller *et al.*, 2003). A quite unusual case

**FIGURE 56.1** Liver metabolism of vitamin K. The dithiol-dependent vitamin K<sub>1</sub> epoxide reduction and vitamin K<sub>1</sub> (phyloquinone) reduction are the metabolic steps inhibited by anticoagulant rodenticides.

is exposure to brodifacoum after donation and transplantation of multiple organs (Ornstein *et al.*, 1999).

The oral bioavailability of warfarin, chlorophacinone, and bromadiolone was estimated to be 79, 92, and 88%, respectively, in sheep. These anticoagulants degraded by approximately 15% over 24h in rumen extracts (Berny *et al.*, 1995). The bioavailability of warfarin is influenced by dietary protein (Barber and Colvin, 1980).

## Distribution

Sixty percent of <sup>14</sup>C-labeled diphacinone is eliminated in feces and 10% in urine over 4 days in mice and 8 days in rats (Yu *et al.*, 1982). Tissue distribution indicated that liver had the most <sup>14</sup>C activity, with the lowest amounts in brain, muscle, blood, and fat (Yu *et al.*, 1982). The disposition and pharmacodynamic properties of brodifacoum have also been characterized in rats (Bachmann and Sullivan, 1983). Similarly, 30% of <sup>14</sup>C-labeled fluocoumafen is eliminated in feces and less than 3% in urine within 3 days in rats (Huckle *et al.*, 1988). Approximately 60% of <sup>14</sup>C fluocoumafen is liable to  $\beta$ -glucuronidase, and most radioactivity is found unchanged in the liver. Elimination is biphasic, with a rapid phase of 5 days and then a prolonged phase of 100 days in Japanese quail (Huckle *et al.*, 1989a,b).

Alteration of parental behavior was speculated to be a cause of 54% lethality in offspring in the face of 40% lethality of lactating female albino rats dosed with coumatetralyl (Marchini and Turillazzi, 1978). However, passage into milk is an alternative theory.

## Elimination

The different chemical structures give different elimination kinetics for the various anticoagulant rodenticides. Elimination kinetics is estimated from human or animal clinical cases in many instances. Such cases are presented for the 4-hydroxycoumarins, warfarin, brodifacoum, difenacoum, bromadiolone, difethialone, and chlorophacinone.

Warfarin has a terminal half-life of  $5.6 \pm 0.7$  h with a monoexponential decay (Breckenridge *et al.*, 1985). Brodifacoum and difenacoum have a biexponential decay of  $60 \pm 1.9$  and  $83 \pm 10$  h, respectively, in rabbits (Breckenridge *et al.*, 1985). Although a median half-life of brodifacoum elimination has been estimated to be 2.4 days in seven dogs (Robben *et al.*, 1998), the data may reflect the first elimination phase.

A 41-year-old man had a terminal half-life of 11.7 days for difenacoum after covert administration of an unknown amount of the drug (McCarthy *et al.*, 1997). A second individual had a peak serum concentration of 600 ng/ml of difenacoum (Butcher *et al.*, 1992).

A peak serum concentration of 440  $\mu$ g/L and an elimination half-life of 140 h were reported in a 55-year-old man who ate an unknown amount of bromadiolone (Grobosch *et al.*, 2006). Elimination half-lives of 2.2 and 3.2 days have been reported in two dogs with difethialone exposure (Robben *et al.*, 1998). A half-life of 5 days has been reported in sheep dosed with pindone (Robinson *et al.*, 2005).

## Duration

Despite reported elimination half-lives, the duration of anticoagulant effect provides an indication of the clinically relevant treatment times. Brodifacoum and difenacoum cases seem to have the longest duration of anticoagulant effect in animals and humans.

Rabbits are anticoagulated 6 weeks after oral exposure to 1 mg/kg BW brodifacoum (Park and Leck, 1982). Although clotting times were prolonged for 7 months after a person's exposure to an unknown amount of difenacoum (McCarthy *et al.*, 1997), elevated concentrations of vitamin K<sub>1</sub> 2,3-epoxide were detected for 18 months after exposure of two factory workers to brodifacoum and difenacoum despite normal prothrombin times (Park *et al.*, 1986).

Duration of treatment has also been reported for bromadiolone and chlorophacinone cases and for pindone-dosed sheep. A patient exposed to bromadiolone had to be treated for 6 months (Haug *et al.*, 1992). An 18-year-old woman's PT normalized 7 weeks after deliberate ingestion of 100 mg chlorophacinone (Vogel *et al.*, 1988). Pindone has been detected for up to 14 days in blood, 17 days in fat, and 39 days in liver of sheep dosed with it (Robinson, 2005).

## TOXICITY

### Occurrence

Anticoagulant rodenticides comprise the most common rodenticide exposure of dogs and the most common toxins seen in many U.S. veterinary practices (Beasley and Trammel, 1989; Murphy *et al.*, 1989). Dogs suspected of anticoagulant rodenticide poisoning in the Netherlands had brodifacoum (19), bromadiolone (14), difenacoum (8), difethialone, and (6) chlorophacinone (1) (Robben *et al.*, 1997). Assessment of potential toxicity of pindone for domestic animals has also been performed (Martin *et al.*, 1991).

### Dose

A 25-year-old man attempted suicide by eating four 42-g boxes of 0.005% brodifacoum bait and succeeded in developing a coagulopathy (Kruse and Carlson, 1992). A 33-year-old man ate 1875 mg of chlorophacinone (Lagrange *et al.*, 1999), and an 18-year-old female deliberately ingested 100 mg chlorophacinone (Vogel *et al.*, 1988) and became anticoagulated. Sheep dosed orally with 10, 3, or 2 mg/kg BW pindone also developed coagulopathies (Robinson *et al.*, 2005). Coumatetralyl poisoning has been reported in pigs (Dobson, 1973) and pest species (Rowe and Redfern, 1968; Greaves and Ayres, 1969).

Rodenticides may be more toxic when repeatedly ingested over several days than when an equal amount is consumed in a single feeding (Dorman, 1990). Susceptibility may be greater in hypoprothrombinemic juveniles or animals with malabsorption syndromes. Also, the concurrent administration of highly protein-bound drugs (e.g., phenylbutazone and aspirin) or disease states, such as chronic renal disease, may increase the susceptibility of individuals to anticoagulant rodenticide poisoning (Beasley and Buck, 1983; Mount *et al.*, 1985). Transdermal exposure is a rare but not unprecedented route of exposure for toxicosis (Binks and Davies, 2007).

## DIAGNOSIS

### History

A clinical diagnosis of anticoagulant rodenticide poisoning is most often dependent on a history of exposure or clinical signs, evidence of a coagulopathy, and response to vitamin K<sub>1</sub> therapy. The most pragmatic approach for determining the specific anticoagulant rodenticide involved is to read the product package. This approach alone is not definitive because as many as 25% of

anticoagulant rodenticide-intoxicated dogs do not have the anticoagulant from the serum the owners suspect (Murphy and Gerken, 1989).

Most anticoagulant rodenticide toxicoses is accidental; however, some is intentional (Mack, 1994) in both humans and animals (Misra *et al.*, 2010). For example, in the United States in 2004, 16,054 cases of exposure were reported as accidental ingestions by children; however, 4576 cases required hospitalization, 23 had major adverse outcomes, and there was one death (Binks and Davies, 2007).

Intent may become a legal issue in malicious poisoning cases. Spontaneous hemorrhage after accidental brodifacoum exposure in a child is known to rarely occur (Watts *et al.*, 1990; Travis *et al.*, 1993; Beriain Rodríguez *et al.*, 2008). Iatrogenic cases in adults occur with more frequency (Weitzel *et al.*, 1990; Waijen *et al.*, 2001; Walker and Beach, 2002; Moery and Pontious, 2009; Hong *et al.*, 2010), and combinations of anticoagulant rodenticides and glass (Tsutaoka *et al.*, 2003) or ethylene glycol (Seidemann *et al.*, 1995) also occur. As many as three different compounds have been detected in one woman (Zolcinski *et al.*, 2008). Human bromadiolone toxicosis has been reported in China (Shi *et al.*, 2005) and is known elsewhere (Shanberge, 1988). Consequently, a history of exposure or lack thereof is not always present or reliable.

## Clinical signs

A history of exposure to anticoagulant rodenticides is not always available, so the toxicity must be inferred from the clinical signs. Clinical signs have been reported in a number of human and animal cases. Humans have dosed themselves or their children (Babcock *et al.*, 1993). Anticoagulant rodenticides have been added to potentiate drugs of abuse (Spahr *et al.*, 2007). Most are related to the coagulopathy. Animals exposed to toxic doses of anticoagulant rodenticides remain asymptomatic until depletion of the active clotting factors occurs. Therefore, clinical signs generally do not develop until 1 or 2 days (Dorman, 1990) or 3–5 days (Murphy and Gerken, 1989) postingestion.

A 55-year-old man had red sputum after ingesting an unknown amount of bromadiolone (Groboch *et al.*, 2006). Epistaxis, gingival bleeding, widespread bruising, hematomas, hematuria, menorrhea, gastrointestinal bleeding, rectal bleeding, hemorrhage into all body organs, and anemia have been reported (Watt *et al.*, 2005). A 36-year-old woman had abdominal pain, hematuria, and red blood in her stool with diffuse cutaneous hematomas after ingesting difenacoum for several weeks. She had hemoperitoneum, urethral hematoma on tomography (Barlow *et al.*, 1982; Berry *et al.*, 2000; Terneu *et al.*, 2003), and diffuse alveolar hemorrhage (Barnett *et al.*, 1992). Hemoperitoneum after fluconazole

administration has been reported in a brodifacoum exposure case (Kim *et al.*, 2010). Hematuria was reported in eight of nine patients who ingested superwarfarins (Nelson *et al.*, 2006; Wu *et al.*, 2009). A case of hemarthrosis has also been reported (Kotsaftis *et al.*, 2007).

A 51-year-old woman who later admitted chronic ingestion of difenacoum was admitted with hemoperitoneum and intramural hematoma of the small intestine (Soubiron *et al.*, 2000). In another case, epistaxis, hematoma, purpura and bruising were observed in a 41-year-old man with difenacoum (McCarthy *et al.*, 1997; Laposata *et al.*, 2007). Frank hematuria (Butcher *et al.*, 1992), neck pain, and cervical hematoma have also been observed in humans with diphenacoum exposure (Nighoghossian *et al.*, 1990). Acquired coagulopathy has been reported due to anticoagulant rodenticide exposure (Humphry, 1989; Huic *et al.*, 2002).

Human pleural, pericardial, mediastinal, and sub-arachnoid hemorrhages are reported with brodifacoum exposure (Kruse and Carlson, 1992), and gastric and pulmonary hemorrhage (Olmos and López, 2007) and hematemesis have been reported (Dolin *et al.*, 2006). Cases of chlorophacinone poisoning in humans have also been reported (Murdoch, 1983; Dusein *et al.*, 1984). Hemoperitoneum from brodifacoum overdose has been observed (Morgan *et al.*, 1996; Kim *et al.*, 2010). Gastrointestinal hemorrhage has been reported after endoscopic cold mucosal biopsy (Zhao *et al.*, 2010). A case of intestinal obstruction associated with superwarfarin poisoning has been reported (Nie *et al.*, 2010). Bruising, hematuria, and abdominal pain secondary to a perinephric hematoma have also been reported (Kapadia and Bona, 2008). A number of other cases of brodifacoum (Braithwaite, 1982; Corke, 1997; Stanziale *et al.*, 1997; Casner, 1998; Bruno *et al.*, 2000), bromadiolone (Chow *et al.*, 1992), and other anticoagulant rodenticide exposure are present in the human literature (Ross *et al.*, 1992).

Clinical signs in animals are largely from canine cases (Woody *et al.*, 1992). Sometimes the only clinical signs in anticoagulant poisoned animals are dyspnea, lethargy, or anorexia, but more often depression, weakness, pallor, and ventral hematomas are present (DuVall *et al.*, 1989). In addition, pulmonary edema, pleural effusion, pericardial effusion (Schulman *et al.*, 1986), intratracheal hemorrhage (McGuire *et al.*, 1999), thymic hemorrhage (Elsinghorst, 2003), laryngeal obstruction (Peterson and Streeter, 1996), pericardial effusion and cardiac tamponade (Petrus and Henik 1999), renal subcapsular hemorrhage (Radi and Thompson, 2004), and hematometra (Padgett *et al.*, 1998) have been reported.

Additional cases of diphacinone (Schulman *et al.*, 1986; Troy, 1988) and brodifacoum toxicosis (Grayson, 1982; McSporran and Phillips, 1983; Booth, 1989; Baker *et al.*, 2002) in dogs are reported. Horses have been exposed to these rodenticides experimentally (Boermans *et al.*, 1991)

and in the field (McConnico, 1997; Ayala *et al.*, 2007). Brodifacoum may have been observed in neonatal puppies (Munday and Thompson, 2003) and has been successfully treated in a pregnant bitch (Hornfeldt and Phearman, 1996).

In clinical settings, prolonged bleeding from injection sites is usually noticed. A few clinical signs are reported that are not directly attributable to the coagulopathy. A paradoxical venous thrombosis was reported in a person with chlorophacinone exposure (Papin *et al.*, 2007). Death, reduced breeding performance, stillborn and non-viable lambs, as well as reduced sperm motility of rams are reported in sheep dosed with pindone (Robinson *et al.*, 2005).

## Coagulopathy

Evidence of a coagulopathy is the second element of the diagnosis. Coagulation tests are normally run on live animals, and a necropsy is performed on dead animals to support the presence of a coagulopathy. The basic mechanisms of clotting have been reviewed (Seegers, 1969).

## Hematology

The anticoagulant rodenticides reduce activity of factors II, VII, IX, and X in circulation. For example, activities of 5% for factor II, 8% for factor VII, 4% for factor IX, and 6% for factor X have been reported in a brodifacoum case (Wu *et al.*, 2009; Kim *et al.*, 2010). The one-stage prothrombin time (OSPT) for evaluating factor VII is the most sensitive tool for early diagnosis because factor VII has the shortest half-life of the vitamin K<sub>1</sub>-dependent clotting factors – approximately 6.2h in dogs. Activated partial thromboplastin time (aPTT) tests for all coagulation factors except factor VII are usually used in conjunction with OSPT. Activated coagulation time (ACT) is used in the same way as aPTT. ACT is easiest to use in a clinic setting because it requires only diatomaceous earth tubes and a heater block or water bath (Byrne, 1970).

Laboratory test results of abnormal prolonged OSPT, aPTT, and ACT in the presence of normal thrombin time (TT), fibrinogen, circulating fibrin degradation products (FDPs), and platelet counts are consistent with anticoagulant rodenticide poisoning. However, animals with severe anemia may have elevated FDPs and reduced platelet counts. An elevated INR is frequently measured in human coagulopathy cases (Schmeits *et al.*, 2009; Boettcher *et al.*, 2011). Thrombosis is rarely reported (Papin *et al.*, 2007; De Paula *et al.*, 2009).

The diagnostic protocol based on these coagulation factor evaluation tests (OSPT, aPTT, and ACT) cannot differentiate between short- and long-acting anticoagulant rodenticide poisoning. The ability to recognize long-acting anticoagulants is critical because therapeutic

success may be based on the duration of vitamin K<sub>1</sub> treatment. The ability to identify the specific anticoagulant rodenticide involved using analytical chemistry is discussed later.

Coagulation testing is not always indicated after minor exposure. Of 110 children who ingested anticoagulant rodenticides, 8 had prolonged PTs. Seventeen percent (6 of 34) had prolonged PTs 48h after exposure, whereas only 1.9% (2 of 104) had prolonged PTs 24h after exposure. It is recommended to check PTs 24 and 48h after exposure in children (Smolinske *et al.*, 1989). Routine measurement of the INR is unnecessary in young children because the amounts ingested are invariably small (Watt *et al.*, 2005).

Although some bias in pediatric brodifacoum exposure data is suspected (Osterhoudt and Henretig, 2003), prospective studies of acute, unintentional, pediatric superwarfarin ingestions managed without (Ingels *et al.*, 2002) or with (Smolinske *et al.*, 1989) decontamination have been conducted. Some argue against the need for a PT in unintentional pediatric superwarfarin exposures (Mullins *et al.*, 2000; see also cases of acute pediatric brodifacoum ingestions (Shepherd *et al.*, 2002)). Although less treatment is often better for accidental pediatric brodifacoum exposures (Kanabar and Volans, 2002), some pediatric cases have coagulopathies despite early treatment (Montanio *et al.*, 1993).

In all other cases, the INR should be measured 36–48h postexposure. If the INR is normal at this time, even in the case of long-acting formulations, no further action is required (Watt *et al.*, 2005).

The most significant elevation of PT, PTT, and protein induced by vitamin K absence (PIVKA) was observed 72h after a single dose of diphacinone of 2mg/kg in ground squirrels (*Spermophilus beecheyi*), although elevations were seen at 24h (Whisson and Salmon, 2002). Increases in ACT, aPTT, and OSPT are often used to support a clinical diagnosis of anticoagulant rodenticide poisoning in dogs (Dorman, 1990). Coagulation factor synthesis may be inhibited for up to 30 days in diphacinone-exposed dogs (Mount and Feldman, 1983).

Prothrombin time should be checked 48h after stopping vitamin K<sub>1</sub> therapy to detect any recurrence of coagulopathy (Chataigner *et al.*, 1989). PTs in sheep were stable in samples stored at 0°, 20°, and 30° for 24h (Shlosberg and Egyed, 1985).

Vitamin K-dependent factor activity has been suggested for rapid identification of surreptitious brodifacoum poisoning (Miller *et al.*, 2006).

## Necropsy/autopsy

Pleural, pericardial, mediastinal, and subarachnoid hemorrhages have been reported in humans with

brodifacoum exposure (Kruse and Carlson, 1992; Tahir *et al.*, 2008).

Hemoperitoneum, hemothorax, and pulmonary hemorrhage are the most common necropsy findings in dogs and cats with anticoagulant rodenticide residues in liver (DuVall *et al.*, 1989; Rickman and Gurfield, 2009). Pulmonary edema, pleural effusion, pericardial effusion (Schulman *et al.*, 1986), and intratracheal hemorrhage are reported as well (McGuire *et al.*, 1999).

Many cases of anticoagulant poisoning are subacute in nature, but sudden death may occur as the result of acute internal hemorrhage. Evidence of external hemorrhage, such as melena, epistaxis, hematemesis, hematuria, gingival bleeding, or excessive bleeding from an open wound, may or may not be seen. However, internal hemorrhage involving the lungs, pleural and/or peritoneal cavities, and facial planes is commonly reported (DuVall *et al.*, 1989; Murphy and Gerken, 1989). Massive tracheal and esophageal hemorrhage 2 days after bait ingestion has been reported in a dog (Stowe *et al.*, 1983). In New Zealand, where brodifacoum was used in wild rabbit population control, 43 rabbit carcasses were found with massive hemorrhage in the abdominal cavity (52%) and thoracic cavity (17%), and the remaining 31% of cases were found with hemorrhage of muscles, cecum, stomach, kidney, mesentery, and placenta of pregnant does (Rammell *et al.*, 1984). Postmortem findings in warfarin poisoning have been described by Dakin (1968).

#### Response to vitamin K<sub>1</sub> treatment

Remission of the coagulopathy 24h after vitamin K<sub>1</sub> treatment supports a clinical diagnosis of a vitamin K<sub>1</sub>-responsive coagulopathy (Tvedten, 1989). A clinical diagnosis is not sufficient in all cases. Some cases require that an etiological diagnosis be made. Analytical chemistry testing is required in such cases.

#### Analytical chemistry

A number of analytical methods have been reported for detecting anticoagulant rodenticides in various matrices. Fluorimetric and gas chromatography methods have been commonly used to detect warfarin in serum (O'Reilly *et al.*, 1962; Corn and Berberich, 1967; Lewis *et al.*, 1970; Welling *et al.*, 1970; Mildha *et al.*, 1974; Vessell and Shivley, 1974; Fasco *et al.*, 1977; Hanna *et al.*, 1978; Lee *et al.*, 1981).

Warfarin-specific methods were generally not adequate for the anticoagulant rodenticides, so a number of other methods were developed, including thin-layer chromatography (TLC), HPLC, mass spectroscopy (MS), and antibody-mediated tests. Coumarin

anticoagulant rodenticides were initially detected using TLC (Lau-Cam and Chu-Fong, 1972; Mallet *et al.*, 1973). A high-performance TLC method with an estimated detection limit of 200 ppb and 87% recovery from liver has been reported (Berny *et al.*, 1995).

Early HPLC methods were focused on an individual chemical. For example, methods to detect chlorophacinone in formulations (Grant and Pike, 1979; Gy *et al.*, 1981), brodifacoum in serum (Murphy and Gerken, 1989), brodifacoum (Koubek *et al.*, 1979; Keiboom and Rammell, 1981; Hoogenboom and Rammell, 1983; Ray *et al.*, 1989; Hong *et al.*, 2010; Kim *et al.*, 2010), bromadiolone (Hunter *et al.*, 1988; Subbiah *et al.*, 2005), chlorophacinone (Hunter, 1984), difethiolone (Goldade *et al.*, 1998), and difenacoum (Mundy and Machin, 1977) in tissue have been reported. Then a method was developed to search for all the anticoagulant rodenticides on the market at the same time. It succeeded in extracting and detecting eight anticoagulant rodenticides in serum and liver using fluorescence and ultraviolet (UV) detection. Samples are extracted with acetonitrile and then cleaned up on solid-phase columns. Four hydroxycoumarins are detected by fluorescence with excitation at 318 nm and emission at 390 nm. The indanediones are detected at 285 nm. An extraction recovery of 75% for serum and 69% from liver was reported. Hydroxycoumarins may be detected down to approximately 1 ng/ml of serum and 1 ng/g of liver, and indanediones may be detected down to 10 ng/ml of serum and 10 ng/g of liver (Felice and Murphy, 1989; Felice *et al.*, 1991; Chalermchaikit *et al.*, 1993). Another HPLC method for detecting brodifacoum in serum and liver using difenacoum as the internal standard has been reported (O'Bryan and Constable, 1991). A method for the simultaneous detection of five superwarfarin rodenticides in human serum has been described by Kuijpers *et al.* (1995). Other serum methods have been reported with detection limits of 3–12 ng/ml for fluorescence and 20–75 ng/ml for UV detection (Mura *et al.*, 1992; Kuijpers *et al.*, 1995; McCarthy *et al.*, 1997; Feng *et al.*, 1999; Jin *et al.*, 2007).

Tissue methods include a solid-phase cartridge extraction from liver with recoveries ranging from 52% for difenacoum to 78% for warfarin. The limit of detection is 10 ppb for warfarin and difenacoum and 110 ppb for chlorophacinone (Addison, 1982; Jones, 1996; Fauconnet *et al.*, 1997).

HPLC methods have also been published to distinguish *cis* and *trans* isomers of difenacoum with detection limits of 5 ng/ml (Kelly *et al.*, 1993). An early interesting approach was the use of a post-column pH shift to enhance fluorescence detection (Hunter, 1985; Hunter *et al.*, 1988). Several HPLC methods have also been reported (AOAC, 1976a,b; Mundy and Machin, 1982; Hunter *et al.*, 1983a,b) for diphacinone (Bullard *et al.*, 1975, 1976) with fluorescence detector for bromadiolone

(Deepa and Mishra, 2005), brodifacoum (Hagenboom and Rammell, 1983; Fu *et al.*, 2006), and difenacoum (Hadler and Shadbolt, 1975) and for determination of Rozol in parafinized formulations (Kawano and Chang, 1980) and bromadiolone in tissues (Nahas, 1986).

Another method uses diode array detector (Yang *et al.*, 2001). An interesting method uses HPLC to detect anticoagulant rodenticides in soft drinks (Dimuccio *et al.*, 1991). Also, an ion pair liquid chromatography method has been reported to detect chlorophacinone and diphacinone in oats (Primus *et al.*, 1998).

Contemporary confirmatory methods use mass spectrometry. Liquid chromatography–electrospray ionization–mass spectroscopy (LC-ESI-MS) has been reported for the analysis of 10 anticoagulant rodenticides with a limit of quantitation of approximately 5 µg/L (Grobosch *et al.*, 2006; Jin and Chen, 2006; Jin *et al.*, 2007). Other methods use LC-MS-MS for drugs including warfarin (Marquet *et al.*, 2003) and flocoumafen (Boettcher *et al.*, 2011) and use LC-ESI-MS and HPLC-UV to detect anticoagulant rodenticides as low as 20 ng (Mesmer and Flurer, 2000). One of the earlier MS methods used a direct probe technique to detect indanedione residues in food animals (Braselton *et al.*, 1992).

A cell culture/enzyme-linked immunosorbent assay has been developed to detect anticoagulant rodenticides in treated grain (Lawley *et al.*, 2006). A prior immunoassay was developed to detect diphacinone and chlorophacinone (Mount *et al.*, 1988). Enantiomers of warfarin, coumachlor, and coumafuryl can be separated chromatographically (Armstrong *et al.*, 1993).

The serum concentration in dogs with anticoagulant rodenticide poisoning ranges from 10 to 851 ng/L for brodifacoum, difethialone, and difenacoum (Robben *et al.*, 1998).

## TREATMENT

General, supportive, and specific treatments are available for anticoagulant rodenticide toxicosis. A prospective study of the outcome of patients with excessive warfarin exposure is described by Hylek *et al.* (2000).

### General

Emetic, adsorbent, and cathartic therapies are indicated if the ingestion of the anticoagulant rodenticide has occurred within the past few hours. Peak serum concentrations of brodifacoum occur 2 h after oral dosing, however, so the coagulation status of the animal should be monitored at 24 and 48 h after exposure.

Clinical coagulopathy normally occurs 2–5 days after oral exposure, so emetics and cathartics at the time of presentation are not normally indicated. Oral-activated charcoal therapy, however, may be useful for those chemicals that undergo enterohepatic circulation.

### Supportive

Recommendations for humans with anticoagulant rodenticide toxicosis have been reported by Watt *et al.* (2005). If active bleeding occurs, 50 units/kg prothrombin complex concentrate (which contains factors II, VII, IX, and X) or 1.2–4.8 mg recombinant activated factor VII, or 15 mL/kg fresh frozen plasma if no concentrate is available, and 10 mg phytonadione intravenously (100 µg/kg BW in a child) should be given. If there is no active bleeding and the INR is 4.0 or less, no treatment is required; if the INR is greater than 4.0, 10 mg phytonadione should be administered intravenously (Watt *et al.*, 2005).

Animals with severe clinical bleeding or markedly reduced PCVs should receive fresh plasma or blood transfusions because of the 4–8 h often required to increase clotting factor activity following vitamin K<sub>1</sub> therapy (Chalermchaikit *et al.*, 1993). These recommendations are consistent with those of other studies (McCarthy *et al.*, 1997; Soubiron *et al.*, 2000; Terneu *et al.*, 2003).

### Specific

Vitamin K<sub>1</sub> therapy is recommended in humans (McCarthy *et al.*, 1997; Soubiron *et al.*, 2000; Terneu *et al.*, 2003; Boettcher *et al.*, 2011) and animals with elevated coagulation times after exposure to anticoagulant rodenticides (Mount *et al.*, 1982; Murphy *et al.*, 1989; Robben *et al.*, 1998). Vitamin K<sub>1</sub> (phyloquinone) is the most effective form for the treatment of anticoagulant rodenticide intoxication because of its immediate availability for the synthesis of new clotting factors (Chalermchaikit *et al.*, 1993).

The pharmacological half-life of vitamin K<sub>1</sub> is  $1.7 \pm 0.1$  h in rabbits dosed with brodifacoum (Park and Leck, 1982). Prothrombin activity reaches peak improvement 4 h after administration of vitamin K<sub>1</sub> to rabbits anticoagulated with brodifacoum or difenacoum (Park and Leck, 1982).

The duration of vitamin K<sub>1</sub> treatment is prolonged for the longer acting chemicals (Butcher *et al.*, 1992). It may be required for up to 2 weeks in diphacinone-exposed dogs (Mount and Feldmam, 1983). Daily doses of vitamin K<sub>1</sub> in the range of 0.25–2.5 mg/kg for 1 week are recommended for exposure to short-acting rodenticides, and doses of 2.5–5.0 mg/kg for 3 or 4 weeks are

recommended for exposure to long-acting rodenticides (Mount *et al.*, 1985). Prolonged anticoagulation in rat poisoning has been reported by Jones *et al.* (1984) and Lipton and Klass (1984). Treatment for 48 days has been reported in a human case of flocoumafen exposure in which a half-life of 6.7 days was estimated (Boettcher *et al.*, 2011). In intentional poisoning cases in humans, vitamin K<sub>1</sub> treatment may be required for 2 months (Dolin *et al.*, 2006) or 3 months (Wu *et al.*, 2009). A brodifacoum case had a 56-day half-life (Olmos and López, 2007).

The two most commonly recommended routes of vitamin K<sub>1</sub> administration are oral and subcutaneous. Intramuscular injections in a hypoprothrombinemic animal can produce hematoma, and intravenous administration of vitamin K<sub>1</sub> has been associated with anaphylaxis; therefore, these routes are discouraged in the therapeutic regimen (Clark and Halliwell, 1963).

Vitamin K<sub>1</sub> therapy may be reduced in a stepwise manner as long as the PT remains normal (Robben *et al.*, 1998). The length of treatment is currently determined by evaluation of OSPT values for 2 days after the cessation of vitamin K<sub>1</sub> administration. If prolonged OPST is found, treatment is commonly continued for another week, but if it remains normal for 5 or 6 days, the vitamin K<sub>1</sub> treatment is usually terminated (Murphy *et al.*, 1989).

A diagnostic approach to the bleeding patient has been described by Johnstone (1989). A diagnostic protocol should utilize more than one coagulation test because it is necessary to differentiate rodenticide poisoning from other coagulopathies, such as disseminated intravascular coagulopathy, congenital factor deficiencies, hyperviscosity syndromes, platelet deficiencies or functional defects, von Willebrand's disease, and canine ehrlichiosis. Hypovitaminosis K associated bleeding has been reported in cats with malabsorption syndrome (Edwards and Russell, 1987).

## CONCLUSIONS

Warfarin was the first anticoagulant rodenticide introduced into the market soon after World War II and was widely used in many countries. Many other anticoagulant rodenticides with similar potency to that of warfarin were also synthesized (LD<sub>50</sub>s ranging from 10 to 50 mg/kg BW). These compounds were recognized as the first-generation anticoagulant rodenticides. Due to the problem of tolerance development in rodents, newer compounds with a greater toxicity (acute LD<sub>50</sub>s of 0.2–3.9 mg/kg) were developed. These compounds are called second-generation anticoagulant rodenticides or superwarfarins. Based on chemical structures,

anticoagulant rodenticides are classified into two categories: hydroxycoumarines and indanediones. Common examples of the former group are brodifacoum, bromadiolone, coumatetralyl, difenacoum, and warfarin, and examples of the latter group are chlorofacinone and diphacinone. Whereas intentional poisoning is common in dogs, secondary poisoning is common in avian and wildlife species. The mechanism of action of all anticoagulant rodenticides is similar to that of warfarin – that is, inhibition of vitamin K<sub>1</sub> epoxide reductase, resulting in the depletion of vitamin K<sub>1</sub>. Subsequently, this impairs the synthesis of normal clotting factors II, VII, IX, and X, and ultimately coagulopathy ensues due to depletion of vitamin K<sub>1</sub> in the liver. Diagnosis is based on history of rodenticide exposure, clinical signs of hemorrhage and coagulopathy, and chemical confirmation in body tissues or fluids. Treatment includes vitamin K<sub>1</sub> and blood transfusion.

## Non-anticoagulant rodenticides

Ramesh C. Gupta

### STRYCHNINE

#### Introduction

Strychnine is an alkaloid derived from the seeds and bark of a tree, *Strychnos nux-vomica*, that is native to Southeast Asia (India, West Indies, Sri Lanka, and Indonesia) and Australia. Strychnine is also found in *Strychnos ignatii*. Strychnine is a white, odorless, crystalline powder, which has the chemical formula  $C_{21}H_{22}N_2O_2$  and a molecular weight of 334.41. Its structural formula is shown in Figure 57.1.

Nux-vomica/strychnine has been used for at least five centuries for both pests and people. Its major use is as a pesticide (rodenticide, avicide, and insecticide), but it is also used as a therapeutic agent in human ailments (laxative, appetizer, and central nervous system (CNS) stimulant). In addition, strychnine in small amounts is known to be added to LSD, heroin, cocaine, and other "street drugs," and it has been known to cause poisoning (O'Callaghan *et al.*, 1982). In the 1960s, strychnine was the title of a song by the rock band "The Sonics"; the song includes the lines, "Some folks like the water, some folks like the wine; I like the taste of straight strychnine." Strychnine has many names and is sold under various trade names, including Boomer-Rid, Certox, Dog-button, Dolco mouse Ceral, Gopher Bait, Gopher Gitter, Kwik-kill, Stricnina, Mole death, Mouse-nots, Mouse-rid, Mouse-tox, Ro-dex, Strychnos, and Sanaseed. Strychnine poisoning in animals occurs from ingestion of baits designed for use against rodents. The most common domestic animal to be affected is the dog, either through accidental ingestion or through intentional poisoning.

FIGURE 57.1 Structural formula of strychnine.

#### Background

Strychnine was first discovered in Saint-ignatii (*Strychnos ignatii*) beans in 1818 by two French scientists (Joseph-Bienaimé Caventou and Pierre-Joseph Pelletier). *Strychnos ignatii* is a woody climbing shrub found in the Philippines. In general, the beans have the same properties as the species *S. nux-vomica*. Strychnine is also found in other species of *Strychnos* (i.e., *S. colubrine* and *S. tieute*) and is accompanied by another alkaloid brucine. The ripe seeds of *Strychnos* look like flattened discs, which are very hard and covered with satiny hairs. The properties of strychnine are substantially those of the nux-vomica. Strychnine is an extremely toxic alkaloid primarily used to kill rodents, moles, predatory animals, and birds or to trap fur-bearing animals. Pharmaceutically, strychnine is an unjustifiable component of traditional tonics, cathartic pills, and CNS stimulant.

#### Toxicokinetics

Following ingestion, strychnine is readily absorbed from the gastrointestinal (GI) tract, but mainly from the

small intestine. Soon after absorption, strychnine readily distributes to various tissues within 5 min (Reynolds, 1982). Strychnine is readily metabolized in the liver. In fact, the metabolism is rapid enough that approximately two lethal doses can be given over 24 h without cumulative effects. Its half-life has been reported to be approximately 10 h in humans. Elimination of strychnine is also rapid, as its unchanged residue can be detected in the urine within a few minutes of exposure. The elimination constant ( $K_{el} = 0.07\text{h}^{-1}$ ) indicates that 7% of the strychnine in the serum at any one moment would be eliminated in 1 h (Edmunds *et al.*, 1986). Following exposure to a sublethal dose of strychnine, approximately 50% of the dose is eliminated within 6 h (Boyd *et al.*, 1983), 10–20% within 24 h, and almost complete in 48–72 h (Cooper, 1974).

### Mechanism of action

Pharmacologically, because of its bitter taste, strychnine strongly stimulates salivary and gastric secretions. This increases appetite, and as a result, strychnine has been used for a long time to counteract the loss of appetite associated with illnesses.

Strychnine is a potent convulsant. It increases reflex excitability in the spinal cord, which results in a loss of the normal inhibition of spread of motor cell stimulation, so that all muscles contract simultaneously. Strychnine causes excitation of all parts of the CNS. It increases the level of neuronal excitability by interfering with inhibitory influences on the motor neurons. The site of the mechanism of action of strychnine is the postsynaptic membrane. The convulsant action of strychnine is due to interference with the postsynaptic inhibition that is mediated by the amino acid glycine. Glycine is an inhibitory transmitter to motor neurons and interneurons in the spinal cord. Strychnine acts as a selective competitive antagonist to block the inhibitory effects of glycine at the glycine receptors. Studies indicate that strychnine and glycine interact with the same receptor but at different sites. There is also evidence of an increase in brain levels of glutamic acid, an amino acid that acts as a transmitter for excitatory nerve impulses that excite muscle contraction. The result of these effects is that skeletal muscles become hyperexcitable. With a little sound or touch, uncontrollable convulsions and seizures become eminent, followed by suffocation and death. Death occurs due to respiratory failure.

### Toxicity

Strychnine has been studied for acute toxicity in many species, and all species that have been tested have been

TABLE 57.1 Acute toxicity data for strychnine

Species	Route of administration	LD <sub>50</sub> (mg/kg)
Rat	Oral	2.30
Rat	i.p.	2.50
Rat	s.c.	1.20
Rat	i.v.	0.96
Mice	Oral	2.00
Mice	i.p.	0.98
Mice	s.c.	0.474
Mice	i.v.	0.41
Duck	Oral	3.00
Pigeon	Oral	21.00

i.p., intraperitoneal; i.v., intravenous; s.c., subcutaneous.

From NIOSH (1983–1984).

found to be sensitive. Strychnine is an extremely toxic substance, with an LD<sub>50</sub> of 2.3 mg/kg in rats, 2 mg/kg in mice, 0.6 mg/kg in rabbits, and 0.5 mg/kg in cats and dogs. An approximate lethal dose for a dog is 0.75 mg/kg body weight. Thus, 5-g bait having 0.3% strychnine could be enough to kill a 20-kg dog. Toxicity data of strychnine for various animal species are given in Table 57.1.

Among animals, poisoning occurs with greatest frequency in dogs due to accidental ingestion or malicious intent. The onset of signs can occur within 15–30 min or occasionally 60 min after oral exposure, depending on whether the stomach is empty or full. The clinical signs are associated with CNS effects. Onset of signs includes restlessness, anxiety, muscle twitching, and stiffness of the neck. The poisoned dogs usually show the signs of mydriasis, tonic convulsions, contractions of striated muscles, seizures, opisthotonus, and death. The animal becomes sensitive to touch, sound, noise, or any other sudden change in the environment. A minor stimulation can trigger violent convulsions. Muscular contractions are easily triggered by external stimuli, accompanied by hypothermia, lactic acidosis, rhabdomyolysis and consequent nephrosis, which may result in renal failure (Gupta and Crissman, 2012).

Although strychnine has no direct effects on skeletal muscles, all voluntary muscles contract simultaneously. The increase in muscle tone is caused by the central action of strychnine. The most powerful effects are seen on the muscles of joints. Respiratory muscles (diaphragm, thoracic, and abdominal) contract, respiration ceases, and eventually death ensues due to respiratory failure.

Birds poisoned by strychnine exhibit the signs of ataxia, ruffled feathers, wing droop, salivation, tremors, and convulsions. Death occurs due to respiratory failure. On postmortem, lesions are only observed in the lungs – that is, pinpoint hemorrhages resulting from death due to asphyxia. Rigor mortis occurs soon after death and persists for days. Occasionally, wildlife species are also inadvertently poisoned by strychnine.

There is no evidence of cumulative toxicity from strychnine (Gosselin *et al.*, 1984). From animal studies,

there is no evidence that strychnine has potential for reproductive and developmental toxicity or mutagenic and carcinogenic activity.

### Diagnosis

Diagnosis of strychnine poisoning is based on (1) history of exposure to a strychnine bait or the presence of cracked corn in the digestive tract; (2) clinical signs of tetanic convulsions, seizures, hypersensitivity to external stimuli, and muscle stiffness; and (3) chemical identification of strychnine in the stomach content, blood, urine, or visceral organs (liver and kidney). Strychnine residue can be detected and quantified using gas chromatography (GC)–flame ionization detector or GC–mass spectrometry. It is important to note that strychnine causes elevation of serum enzymes, including glutamic oxaloacetic transaminase, creatine phosphokinase, and lactate dehydrogenase. In addition, lactic acidosis, hyperkalemia, and leukocytosis are the characteristic laboratory findings. In differential diagnosis, tetanus must be ruled out.

### Treatment

There is no specific antidote for strychnine poisoning, so treatment rests with symptomatic and supportive therapies. Seizures need to be controlled as soon as possible with diazepam or phenobarbital. Artificial respiration can be used for apnea. Once the seizures are controlled, detoxification can be performed using gastric lavage with potassium permanganate. Give activated charcoal with a saline cathartic to stop further absorption in the GI tract. Animals should be kept in a quiet environment and should be protected from any secondary sensory input.

### Conclusion

Strychnine is an extremely toxic plant alkaloid that is primarily used as rodenticide. Due to inadvertent use or malicious intent, the poisoning is frequently encountered in dogs. Onset of clinical signs occurs very quickly, and the poisoning is characterized by convulsions, seizures, and hypersensitivity to any external stimulus. Treatment is symptomatic and warranted immediately.

## BROMETHALIN

### Introduction

Chemically, bromethalin is a diphenylamine compound with an appearance of a pale, odorless, and

FIGURE 57.2 Structural formula of bromethalin.

solid crystalline powder. It has a chemical formula of C<sub>14</sub>H<sub>17</sub>Br<sub>3</sub>F<sub>3</sub>N<sub>3</sub>O<sub>4</sub>, with a molecular weight of 577.93. Its chemical structure is shown in Figure 57.2. It is commonly used as rodenticide for the control of rats and mice. Bromethalin has many other names and is sold under brand names such as Assault, Trounce, Vengeance, and Wipe Out.

### Background

Bromethalin was developed for use against warfarin-resistant rodents. It is a restricted-use rodenticide used in and around buildings and sewers and inside transportation and cargo vehicles. It is extremely toxic, and only a single dose of bromethalin is needed to cause death in rats and mice. Bromethalin is marketed in a 0.01% formulation (2.84 mg of bromethalin per ounce of bait) and comes in bait pellets, bars, and packs. It is important to note that bromethalin cannot be distinguished from other rodent baits by color or appearance alone. Secondary poisoning usually occurs in dogs and cats that eat a mouse killed by bromethalin.

### Toxicokinetics

Toxicokinetic information on bromethalin is available from laboratory animals such as rats. Bromethalin is rapidly absorbed following oral ingestion. Plasma concentration peaks in approximately 4 h. Metabolism takes place in the liver, where bromethalin undergoes *N*-demethylation, forming desmethyl bromethalin. This metabolite is toxic, as its LD<sub>50</sub> is 7.5 mg/kg body weight. The plasma half-life of bromethalin is approximately 6 days (Dorman *et al.*, 1990c), suggesting slow elimination. Excretion occurs mainly in bile, as it enters into enterohepatic circulation.

### Mechanism of action

Bromethalin is a neurotoxicant and affects the CNS. It uncouples oxidative phosphorylation in the mitochondria,

thereby decreasing ATP synthesis. With a marked decrease in ATP, very little energy is available to maintain  $\text{Na}^+/\text{K}^+$ -ATPase pump. As a result, cells lose their ability to maintain osmotic control,  $\text{Na}^+$  is retained intracellularly, and the cells swell with water. This leads to fluid accumulation within myelin sheaths and vacuolation of the nervous system, resulting in nerve conduction impairment. Damage to neuronal axons and increased intracranial pressure occur, followed by convulsions, paralysis, and death (Dorman *et al.*, 1992).

## Toxicity

Bromethalin is a single-dose rodenticide. It is classified as highly toxic if swallowed, inhaled, or absorbed through skin. The acute oral  $\text{LD}_{50}$  of bromethalin is 2.38–5.6 mg/kg in bait for dogs and 0.4–0.71 mg/kg in bait for cats (Dorman *et al.*, 1990c). Its  $\text{LD}_{50}$  is 2 mg/kg in mice, 5 mg/kg in rats, 13 mg/kg in rabbits, and 0.25 mg/kg in pigs.

In field cases, most often poisoning occurs in pets, including dogs and cats. Signs of bromethalin appear within 10 h to several days after exposure and may last up to 12 days. In most cases, the poisoning is acute in nature, characterized by cerebral edema and paralysis of the hind limbs. In general, clinical signs in pets include severe muscle tremors, hyperexcitability, hyperesthesia (hypersensitivity to touch), and seizures. Symptoms with mild exposure to bromethalin occur with slow progress in several days, and they include loss of ability to bark, loss of appetite, vomiting, depression, lethargy, tremors, paralysis, lateral recumbency, coma, and death. Following exposure to a large dose of bromethalin, animals can show signs of muscle tremors and seizures, hyperexcitability, ataxia and paddling, hyperthermia, potential loss of vocalization, loss of tactile sensation, and forelimb extensor rigidity (Schiff–Sherrington posture), and death occurs within 2–4 days. Death can occur with a low or high dose, and is usually caused by respiratory paralysis. Poisoned dogs show the signs of tremors, ataxia, depression, tachypnea, hyper-reflexia of the hind limbs, loss of vocalization, recumbency, anorexia, vomiting, and death (Dorman *et al.*, 1990a). Poisoned cats exhibit the signs of ataxia, seizures, vocalization, rigidity, decreased proprioception, abdominal distension, recumbency, depression, and death (Dorman *et al.*, 1990b, 1992). Other signs of poisoning include generalized seizures, head pressing, hyperesthesia, coma, hyperexcitability, ataxia, extensor rigidity, nystagmus, hyperthermia, cyanosis, miosis, and drooling (Moorman, 2003). Overall, cats are much more sensitive than dogs to bromethalin.

Histopathological changes have been described in dogs receiving a single oral dose of bromethalin

(6.25 mg/kg). Histologic lesions included diffuse white matter spongiosis, mild microgliosis, optic nerve vacuolization, mild thickening of Bowman's capsule, and occasional splenic megakaryocytes. Ultramicroscopic examination of mid-brain stem revealed occasional swollen axons, intramyelinic vacuolization, and myelin splitting at the intraperiod line (Dorman *et al.*, 1990c). Dorman *et al.* (1992) also reported histopathological changes in cats induced by bromethalin. In brief, ultrastructural changes include separation of myelin lamellae at the interperiod lines with the formation of intramyelinic vacuoles (intramyelinic edema), rupture and coalescence of intramyelinic vacuoles into larger extracellular spaces (spongy change), and pronounced cytosolic edema of astrocytes and oligodendroglial cells. Histopathology of the brain and spinal cord of rodents receiving multiple low or sublethal doses of bromethalin revealed a spongy degeneration of the white matter that was shown upon ultramicroscopic examination to be intramyelinic edema (Van Lier and Cherry, 1988).

According to the World Health Organization and the U.S. Environmental Protection Agency, bromethalin is considered carcinogenic.

## Diagnosis

Diagnosis of bromethalin poisoning is based on history of exposure to bromethalin bait, clinical signs, and identification of bromethalin in bait, GI content, brain, and visceral organs. Residue of bromethalin or its major metabolite (desmethyl bromethalin) can be quantified using GC coupled with electron capture detector (Dorman *et al.*, 1990c) or high-performance liquid chromatography (HPLC) coupled with ultraviolet detector or with negative-ion atmospheric pressure chemical ionization–mass spectrometric detector (Mesmer and Flurer, 2001). The highest concentrations of bromethalin are found in fat, liver, kidney, and brain. Differential diagnosis should rule out lead, ethylene glycol, organophosphates, strychnine, metaldehyde, zinc phosphide, and tremorgenic mycotoxins.

## Treatment

There is no specific antidote for bromethalin poisoning. Symptoms can be treated with corticosteroids, but clinical studies indicate that symptoms return as soon as the corticosteroids are discontinued. Emesis should be induced using apomorphine or 3% hydrogen peroxide if the animal is not exhibiting signs of convulsions and seizures. Alternatively, perform gastric lavage and give activated charcoal with saline cathartic. Activated charcoal needs to be repeated if the dog or cat is exposed to a large dose of bromethalin. The animal needs to be

monitored and treated for cerebral edema. Intravenous fluids can be administered with great caution so as not to worsen cerebral edema. Diazepam or barbiturate can be given to control seizures.

## Conclusion

Bromethalin is a commonly used rodenticide that is encountered in poisoning in dogs and cats. Bromethalin exerts toxicity by uncoupling oxidative phosphorylation in mitochondria, thereby decreasing ATP synthesis. The CNS is the target organ, and toxicity is characterized by cerebral edema, convulsions, and paralysis. There is no specific antidote, so treatment is symptomatic and supportive.

## CHOLECALCIFEROL

### Introduction

Cholecalciferol is a form of vitamin D, also called vitamin D<sub>3</sub>, that is commonly used as rodenticide. Vitamin D<sub>3</sub> is a secosteroid and structurally similar to other steroids, such as cholesterol, testosterone, and cortisol. It has chemical formula C<sub>27</sub>H<sub>44</sub>O, with a molecular weight of 384.64. Its structural formula is shown in Figure 57.3. Cholecalciferol has other names and is marketed as a rodenticide under the brand names Quintox, True Grit Rampage, and Ortho Rat-B-Gone; it is also marketed as a feed additive under the name Viactive.

### Background

Cholecalciferol is a rodenticide that is used in and around buildings and inside transport vehicles. Vitamin D<sub>3</sub>, as such, does not have significant biological activity,

but in two steps, it is metabolized in the body to make an active form. In liver, cholecalciferol is hydroxylated to 25-hydroxycholecalciferol (calcifediol) by the enzyme 25-hydroxylase. In kidney, 25-hydroxycholecalciferol serves as a substrate for 1- $\alpha$ -hydroxylase, forming 1,25-dihydroxycholecalciferol (calcitriol), which is the biologically active form. Cholecalciferol is formulated in the granular form (0.075% bait) and is very effective against Norway rats, roof rats, and house mice.

### Toxicokinetics

Very little information is available on the toxicokinetics of cholecalciferol. Cholecalciferol is transported in blood bound to carrier proteins. The major carrier protein is vitamin D binding protein. The half-life of 25-hydroxycholecalciferol is several weeks, whereas that of 1,25-dihydroxycholecalciferol is just a few hours.

### Mechanism of action

Ingestion of cholecalciferol-containing bait is known to cause a marked increase in calcium level in blood and tissues. Cholecalciferol not only increases the absorption of calcium but also mobilizes calcium and phosphorus from bones to the circulation. High calcium causes heart problems and bleeding secondary to mineralization of the vessels, kidneys, stomach wall, and lungs. Mineralization of the kidney leads to renal failure and death. Cholecalciferol and its metabolites exert their effects by binding to vitamin D receptors in tissues. 1,25-Dihydrocholecalciferol is the most metabolically active form, with 500 times greater binding to the vitamin D receptors than that of 25-hydroxycholecalciferol and 1000 times greater binding than that of cholecalciferol.

### Toxicity

Cholecalciferol is of low toxicity to mammalian species, as it is classified as a class III toxic chemical. The oral LD<sub>50</sub> of cholecalciferol in rats is 43.6 mg/kg and in mice is 42.5 mg/kg. The dermal LD<sub>50</sub> in rabbits is 2000 mg/kg. Studies suggest that cholecalciferol is of low toxicity to birds (oral LD<sub>50</sub> is >2000 mg/kg in mallard ducks and dietary LC<sub>50</sub> is 4000 ppm in mallard ducks and 2000 ppm in bobwhite quail).

Pets such as dogs are poisoned by ingesting rodenticide bait, whereas farm animals are affected by overdose of additive vitamin D<sub>3</sub> in the feed. Signs and symptoms of poisoning are similar to those of hypercalcemia, such as anorexia, fatigue, headache, itching, weakness,

FIGURE 57.3 Structural formula of cholecalciferol.

nausea, vomiting, and diarrhea. In acute cases, cholecalciferol causes severe polyneuropathy. Dogs poisoned with cholecalciferol-containing rodenticide bait usually show signs of depression, anorexia, vomiting, bloody diarrhea, cardiac irregularities, hypertension, seizures, and death. In dogs, signs of poisoning may occur with as little as a 2 mg/kg dose, and death may occur with a 10 mg/kg dose of cholecalciferol.

## Treatment

Decontamination, including induction of emesis, gastric lavage, and administration of activated charcoal, is beneficial. Administration of intravenous fluids helps reduce serum calcium levels by increasing urine production and calcium excretion. Biphosphonate pamidronate disodium is used to decrease serum calcium levels. Seizures can be controlled by diazepam or barbiturates. Treatment needs to be continued for 2 or 3 weeks because the elimination half-life of cholecalciferol is more than 2 weeks. Poisoned animals should receive feed devoid of vitamin D<sub>3</sub>.

## Conclusion

Cholecalciferol is a single- or multiple-dose rodenticide that has low toxicity to mammalian and avian species. It produces toxicity by marked increases in calcium and mineralization of tissues. Once animals develop severe signs, they usually die.

# RED SQUILL

## Introduction

Red squill, which is also known as sea onion, is obtained in the powder form from the plant *Urginea maritima*. The plant is native to the Mediterranean region. It resembles an onion, and its bulb extracts and dried powders have been used for the control of rodents since the 13th century. Although red squill has many alkaloids, scilliroside is the most toxic and provides rodenticidal activity. It has the chemical formula C<sub>32</sub>H<sub>44</sub>O<sub>12</sub> and a molecular weight of 620.7. Its structural formula is shown in Figure 57.4. The compound is sparingly soluble in water and thermostable. Scilliroside is formulated in the powder form (Dethdiet) and liquid extract (Rodine), and it has many other names, including Sea squill, Scilla maritima, Silmurin, Silmine, Sea onion, and Squill. It was demonstrated long ago by Winton (1927b) that only red squill, and not white squill, has rodenticide activity. The red squill is mixed in baits

FIGURE 57.4 Structural formula of scilliroside.

and applied at a 10% concentration and mixed with meat, fish, and cereals (Thomson, 1991–1992).

## Background

Red squill bulbs were an ancient source of rodenticide products replaced later by warfarin and other modern anticoagulant rodenticides. Because rats have developed resistance to such products, there is renewed interest in the red squill. Studies suggest that the white squill drug is used as a diuretic, stimulant, and expectorant, whereas the red squill is used mostly as a rat poison. Many glycosides and aglycones have been isolated from the red squill bulb. Krenn *et al.* (1994) and Pascual-Villalobos (2002) isolated five different bufadienolides as pure substances (proscillaridin A, scillaren A, scilliroside, gam-mabufotalin, and scillirosidin). Scilliroside is the most toxic bufadienolide glycoside (Verbiscar *et al.*, 1986a,b).

Scilliroside has an emetic property. Thus, if rodents ingest a product containing scilliroside, because they are incapable of vomiting, they develop glycoside intoxication and pulmonary edema. However, the compound has rarely been associated with toxicity in humans because humans are capable of vomiting and exhibit poor gastrointestinal absorption.

## Toxicokinetics

Scilliroside is inefficiently absorbed from the GI tract. Its metabolism is not well studied, although the unmetabolized scilliroside is rapidly excreted in the urine.

## Mechanism of action

Red squill bulbs contain many glycosides, but scilliroside is the major component that has a rodenticidal

property. The compound is cardiotoxic, similar to digitalis; that is, injection of scilliroside induces cardiac impulse condition and arrhythmias. In very early experiments, red squill preparations administered to rats induced convulsions and paralysis (Winton, 1927a). Female rats succumb to red squill at half the dose that is required to kill males.

## Toxicity

The red squill plant (mainly the bulb) contains scilliroside, a highly toxic bufadienolide glycoside. It adversely affects cardiovascular and central nervous systems, causing convulsions and death. The oral LD<sub>50</sub> of scilliroside is 0.7mg/kg in male rats and 0.43mg/kg in female rats, and it is 0.35mg/kg in mice. Studies found that pigs and cats survived doses of 16 mg/kg and fowls survived 400mg/kg (Worthing, 1983). It is classified as class I – that is, a highly toxic chemical.

Red squill contains several compounds that have emetic properties. Due to poor gastrointestinal absorption and decreased potency, red squill has seldom been associated with toxicity in humans, dogs, cats, and pigeons. However, rats and mice are unable to vomit, and they die within a few hours after ingesting a lethal dose of scilliroside.

In toxic doses, red squill produces inflammation of the gastrointestinal and genitourinary tracts, manifested by nausea, vomiting, abdominal pain, and purging. Other signs of poisoning include convulsions, hypothermia, enfeebled circulation, blurred vision, and sometimes death. Convulsions are seen in humans, and they have also been observed in rats. Higher doses of red squill can cause serious heart rhythm alterations resulting in death. Farm animals require large quantities for intoxication. There are field cases in which dogs, cats, and pigs have been poisoned. Signs of poisoning include vomiting, ataxia, and hyperesthesia, followed by paralysis, depression, or convulsions. Cardiac arrest occurs due to bradycardia and cardiac arrhythmias. Generally, animals exposed to a sublethal dose can recover in less than 48 h.

## Treatment

Treatment is based on symptomatic and supportive therapies. In case a significant amount of red squill is retained in the stomach, decontamination (gastric lavage with saline cathartic) is rewarding. The patient must be monitored for cardiac arrhythmias and conduction disturbances. Atropine sulfate given subcutaneously at 6- to 8-h intervals may prevent cardiac arrest. Phenytoin at 35mg/kg, TID, should be given to dogs to suppress arrhythmias.

## Conclusions

Red squill is a botanical rodenticide and exerts toxicity due to cardiac effects. Treatment is symptomatic and supportive.

# FLUOROACETATE

## Introduction

Sodium fluoroacetate (compound 1080) is an extremely toxic white powder that has been used as a rodenticide throughout the world. The compound has the chemical formula C<sub>2</sub>H<sub>2</sub>FO<sub>2</sub>.Na, with a molecular weight of 100.02. Its structural formula is shown in Figure 57.5. It is used to control rats, mice, squirrels, prairie dogs, foxes, wolves, coyotes, and rabbits. The compound is also used to control brush-tail possums, deer, wild pigs, wallabies, and rooks. It is very toxic to birds, domestic animals, and carnivores. Secondary poisoning is very common in birds and carnivores from eating poisoned carcasses.

Sodium fluoroacetate has many other names and is sold under trade names such as Nissol, 1080 gel, 1080 paste, 1080 solution, Tenate, and Tenate 1080. The commercial products are provided with a black dye called nigrosine (0.5%).

## Background

Sodium fluoroacetate was discovered by German military chemists during World War II. However, it was not until later that American chemists discovered its use as a rodenticide. The name “1080” refers to the catalog number of the poison, which became its brand name. The compound is an extremely toxic substance, which is commonly used as a rodenticide. Inhalation of dust or swallowing can also be fatal. The compound can also be absorbed through cuts or abrasions in the skin and lead to poisoning.

It is important to note that sodium fluoroacetate is also formed naturally in approximately 40 plants that are native to Australia, Brazil, and Africa after fluoride uptake from soil, water, or air. Examples of plants that contain sodium fluoroacetate are *Dichapentalum cymosum*, *D. toxicarum*, *Chaillietia toxicaria*, *Gastrolobium grandiflorum* (“poison peas”), *Oxylobium parviflorum*, and

FIGURE 57.5 Structural formula of sodium fluoroacetate.

*Acacia georginae*. Consumption of these plants has resulted in many serious cases of livestock poisoning and high stock losses (Oelrichs and McEwan, 1962). Poisoning has also been documented in field-workers exposed to fluoroacetate (Suh *et al.*, 1970).

## Toxicokinetics

Sodium fluoroacetate (1080) is rapidly absorbed from the GI tract. Dust formulations are easily absorbed by inhalation, which is not usually the route for poisoning cases. 1080 is not readily absorbed through intact skin, but it can be absorbed in the case of cuts, abrasions, or dermatitis (Brockman *et al.*, 1955). It is reported that sublethal doses of compound 1080 are completely metabolized and excreted in 4 days.

The bioavailability of sodium fluoroacetate appears to be similar for oral, injected, and inhaled doses. Dermal absorption is lower because a subcutaneous LD<sub>50</sub> is 10- to 15-fold higher than the oral dose. Distribution studies suggest that the plasma levels of sodium fluoroacetate are twice those of tissues. Sheep receiving sodium fluoroacetate (0.1 mg/kg) contained the residue in plasma, kidney, heart, muscle, spleen, and liver as 0.098, 0.057, 0.052, 0.042, 0.026, and 0.021 (Eason *et al.*, 1993). The plasma  $t_{1/2}$  is 3.6–6.9 h in goats, 6.6–13.3 h in sheep, 1.1 h in rabbits, and 1.6–1.7 h in mice (Eason *et al.*, 1993; Gooneratne *et al.*, 1995). Metabolism of fluoroacetate (i.e., defluorination) takes place in the liver. Fluoroacetate and fluorocitrate salts are excreted mainly in the urine.

## Mechanism of action

In the body, fluoroacetate (1080) is converted to fluorocitrate, which is a potent inhibitor of the enzyme aconitase in the tricarboxylic acid cycle (Krebs cycle) (Elliot and Kalnitsky, 1996). As a result, the elevated levels of citrate in blood become observable 30 min and maximum levels at 4 h after administration. It has been shown that citrate levels are directly influenced by thyroid hormone (i.e., free T<sub>3</sub>; Maruo *et al.*, 1992). Accumulation of citrate causes toxicity due to reduction of ATP levels by inhibiting energy production in most cells of the body, leading to a slow and painful death as the body “suffocates from within.” Compound 1080 causes damage to tissue of high energy needs, such as brain, heart, lungs, and fetus.

Accumulated levels of citrate cause chelation of divalent metal ions, especially Ca<sup>2+</sup>. Depletion of these ions in the CNS may be responsible for seizures in certain species (Hornfeldt and Larson, 1990).

Fluoroacetate/fluorocitrate also affects activities of other enzymes, including mitochondrial citrate carriers, pyruvate dehydrogenase kinase (Taylor *et al.*, 1977),

succinate dehydrogenase (Mehlman, 1967), glutamine synthetase, phosphofructokinase (Godoy and del Carmen Villarruel, 1974), and ATP-citrate lyase (Rokita and Walsh, 1983).

## Toxicity

Most species are sensitive to fluoroacetate (1080); however, rodents and dogs are the most sensitive species. The oral LD<sub>50</sub> of 1080 is 0.1–0.22 mg/kg in rats, 0.1 mg/kg in mice, 0.34 mg/kg in rabbits, and 0.3 mg/kg in guinea pigs. The oral LD<sub>50</sub>s of this compound in the house sparrow, red-winged blackbird, starling, and golden eagle are 3.0, 4.22, 2.37, and 1.25–5 mg/kg, respectively. Measured LD<sub>50</sub> of this rodenticide in mammalian wildlife is 0.22–0.44 mg/kg in mule deer, 1.41 mg/kg in male ferrets, and 0.5–1.0 mg/kg in bears.

In general, fluoroacetate is very toxic to mammalian, bird, and wildlife species, whereas it is of low toxicity to fish. Toxicity of 1080 is different according to route of exposure (i.e., ingestion or inhalation), and symptoms vary widely among species. Species have been categorized into four groups according to symptomatology:

1. Rabbit, goat, horse, sheep, and spider monkey: CNS effects are not observed, and death is due to cardiac effects with ventricular fibrillation.
2. Cat, pig, rhesus monkey, and human: Heart and CNS are affected, and death usually results from respiratory failure during convulsions but is occasionally due to ventricular fibrillation.
3. Dog and guinea pig: Epileptiform convulsions predominate, with death being due to cessation of respiratory activity following running movements such as those of strychnine poisoning.
4. Rat and hamster: Respiratory depression and delayed bradycardia are the main features.

In general, 1080 produces convulsions, involuntary urination, vomiting, and ventricular fibrillation. The onset of symptoms of poisoning is usually between 30 min and 4 h after exposure. The common symptoms are vomiting, involuntary hyperextension of the limbs, convulsions, and, finally, cardiac and respiratory failure. Dogs usually show CNS signs such as convulsions and uncontrollable running, whereas sheep and cattle show predominantly cardiac signs. Dogs appear to be highly sensitive to fluoroacetate, and mass poisonings of dogs eating contaminated poultry have been documented (Egyed, 1979).

The main target organs affected are the central nervous, cardiovascular, and respiratory systems. This causes metabolic derangement that includes alteration in transaminase, calcium, and glucose levels apart from acidosis and renal failure.

Clinic effects are associated with neurological and cardiac systems. CNS effects include tremulousness, hallucinations, convulsions, and respiratory depression. Cardiac effects include arrhythmias, ventricular fibrillation, and cardiac arrest. If the patient survives the first 24h after ingestion of sodium fluoroacetate, recovery is favorable. Acute exposure often results in complete recovery or death. Of course, in some cases, exposure results in cardiac damage.

Severity of signs is dose related. The oral route is the most important in cases of poisoning of 1080. Dust formulations are easily absorbed by inhalation, which is not usually the route for poisoning cases. Compound 1080 is not readily absorbed through intact skin, but it can be absorbed in the case of cuts and dermatitis.

The fluorocitric acid is itself highly toxic, and therefore sodium fluoroacetate can cause secondary poisoning – that is, poisoning in an organism that has consumed a part of an organism already poisoned.

The development of tolerance to increasing doses of fluoroacetate has been reported in rats and mice, whereby a dose of 0.5mg/kg protects rats against a dose of 5mg/kg for a period of 48h (Chenoweth, 1949). The mechanism of fluoroacetate resistance in certain species is not well understood, but the rate of defluorination does not appear to play a significant role (Mead *et al.*, 1985).

Studies suggest that sodium fluoroacetate has no carcinogenic, mutagenic, or teratogenic potential.

### Diagnosis

Diagnosis is based on evidence of exposure, clinical signs, necropsy findings, and chemical confirmation. Samples for chemical confirmation should include suspected bait, vomitus, stomach content, liver, and kidney. Testing for 1080 should be performed on the vomited stomach contents. In the case of ruminants, rumen content needs to be analyzed for fluoroacetate. Significant elevation of citric acid levels in blood and kidney is a reliable biochemical marker of fluoroacetate or fluorocitrate poisoning (Basakowski and Levin, 1986). Hyperglycemia, hypocalcemia, and hypokalemia are characteristic laboratory findings. Other metabolic/biochemical changes include metabolic acidosis resulting from a buildup of citric acid, lactic acid, and ammonium in blood and organs. Metabolic acidosis is also associated with elevated serum creatinine and transaminase levels.

Differential diagnosis should include lead, strychnine, chlorinated hydrocarbons, and plant alkaloids.

### Treatment

There is no specific antidote for 1080 poisoning. Use of glyceryl monoacetate has shown some positive results

because it provides acetate ions to allow continuation of the cellular respiration process, which is interrupted by compound 1080. Other symptomatic and supportive measures following decontamination procedures (to prevent further absorption by activated charcoal) include use of anticonvulsants, muscle relaxants, and mechanical ventilation. Induction of emesis is contraindicated because of potential arrhythmias and convulsions. Special attention should be paid to stabilize cardiac and CNS functions.

Acetate and ethanol have been found to be potentially effective in mice, guinea pigs, and rabbits but not in dogs. A combination of calcium gluconate and sodium succinate has proven effective in mice (Omara and Sisodia, 1990). Calcium chloride has antidotal effects in cats (Roy *et al.*, 1980).

### Conclusion

Fluoroacetate converts to fluorocitrate, which is an extremely toxic metabolite. Symptoms vary markedly between species. For example, carnivores exhibit more signs related to the CNS, herbivores exhibit signs related to cardiac effects, and omnivores show signs of both CNS and cardiac effects. Treatment relies on symptomatic and supportive measures.

## ALPHA-NAPHTHYL THIOUREA

### Introduction

Alpha-naphthyl thiourea (ANTU) is a colorless, odorless, crystalline powder that is exclusively used as rodenticide. The technical product is gray powder. Its chemical formula is  $C_{11}H_{10}N_2S$ , and it has a molecular weight of 220.28. Its structural formula is shown in Figure 57.6.

ANTU has several other names, including alpha-naphthyl thiocarbamide, 1-naphthyl-thiourea, *N*(1-naphthyl)-2 thiourea, Alrato, Anturat, Bantu, Dirax, Krysids, Rat-tu, and Rattrack.

### Toxicokinetics and mechanism of action

Following ingestion, ANTU is rapidly absorbed from the GI tract. The exact mechanism of action of ANTU is not known. ANTU stimulates the sympathetic nervous system and causes a major increase in the permeability of the lung capillaries; consequently, extensive pleural effusion and pulmonary edema develop. This results in respiratory failure.

FIGURE 57.6 Structural formula of alpha-naphthyl thiourea.

## Toxicity

All animals are susceptible to ANTU, but lethal doses differ widely. Lethal doses of ANTU (in mg/kg) in various species are as follows: rats (3), dogs (10), pigs (25), horses (30), cows (50), cats (75), and fowl (2500).

Clinical signs of poisoning due to ANTU include vomiting, abdominal pain, dyspnea, shortness of breath, seizures, bluish discoloration, coarse pulmonary rales, pulmonary edema, and liver damage. In a time course study, ANTU at a dose rate of 5mg/kg induced lung edema in adult albino rats (Vivet *et al.*, 1983). After 6h, pulmonary extravascular water increased by 50% in ANTU-treated rats, and the volume of the pulmonary effusion reached  $3.4 \pm 0.1$  mL. The most characteristic feature is the absence of hypoxemia in ANTU-intoxicated rats. The absence of hypoxemia is common with normobaric oxygen. ANTU can produce hyperglycemia of three times normal in 3h.

Chronic sublethal exposure to ANTU may cause enlarged thyroid gland (goiter) and interfere with normal thyroid function. Repeated sublethal doses in rats lead to the development of tolerance so that resistance to several lethal doses develops (Peoples, 1970).

## Diagnosis

Diagnosis of ANTU poisoning is based on evidence of rodenticide exposure, clinical signs, lung and liver damage, and chemical confirmation. ANTU can be quantified using HPLC.

## Treatment

There is no specific antidote. Therefore, treatment relies on symptomatic and supportive measures. Induce vomiting if the patient is not showing convulsions and seizures.

The decontamination procedure includes administration of activated charcoal.

# ZINC PHOSPHIDE

## Introduction

Zinc phosphide is an inorganic compound with the appearance of gray crystalline powder and a decaying

FIGURE 57.7 Structural formula of zinc phosphide.

fish or garlic odor. It has the chemical formula  $Zn_3P_2$ , with a molecular weight of 258.1. Its structural formula is shown in Figure 57.7. Zinc phosphide was first synthesized in 1740 and was first used as a rodenticide in 1911–1912 in Italy. It was not used in the United States until 1939. In the 1970s, there was a renewed interest in zinc phosphide for rodent control in agriculture. Currently, zinc phosphide is used worldwide for the control of a range of animals, including mice, rats, voles, ground squirrels, prairie dogs, moles, muskrats, rabbits, and gophers. Pelleted zinc phosphide is sold extensively under brand names such as Arrex, Blue-ox, Gopharid, Kil-rat, Mous-con, Phosvin, Pollux, Ratol, Ridall, Rodenticide AG, Zinc-tox, and ZP. It is also used on crop/noncrop areas, including lawns, golf courses, and around wetlands.

## Background

The history of the use of zinc phosphide as a rodenticide dates back approximately a century. In the early years, technical zinc phosphide and highly concentrated paste were sold in shops and used by consumers to make their own baits for rodents. This led to use of the technical material for suicide and to accidental deaths in small children and pets.

Zinc phosphide is recognized as the slowest acting of the commonly used rodenticides. It can cause toxicity and death in rodents after one feeding if adequate dose is consumed. However, bait must be continuously available to be effective. In fact, zinc phosphide is recommended as the rodenticide of choice because it is fairly specific for rodents and secondary poisoning is rare, except in dogs and cats.

Rodenticide-grade zinc phosphide usually comes as a black powder containing 75% zinc phosphide and 25% antimony potassium tartrate, an emetic to cause vomiting if the material is accidentally ingested by humans or domestic animals.

## Toxicokinetics

Zinc phosphide can be absorbed into the body by oral ingestion, inhalation, and through damaged skin. Following oral ingestion, zinc phosphide reacts in the stomach and intestine with water and hydrochloric acid to liberate phosphine gas. Metabolism of zinc phosphide

can occur via oxidation of the phosphorus to various phosphorus oxyacids or via reduction of the phosphorus to phosphine gas. Zinc phosphide excretes in the urine either as a hypophosphite or as dissolved phosphine. The presence of strong reducing substance in the urine is a common feature of poisoning with zinc phosphide. Other metabolites include phosphoric acid and phosphate. Phosphine gas is also exhaled from the lungs.

### Mechanism of action

The overall toxicity of zinc phosphide is due to both zinc and phosphine gas, but it is primarily from phosphine. Phosphine can enter the bloodstream and adversely affect the lungs, liver, kidneys, heart, and CNS. Phosphine causes CNS depression, irritation of the lungs, damage to the blood vessels and erythrocyte membranes, and eventually cardiovascular collapse and irritation of the alimentary tract. Zinc phosphide also causes damage to the liver and kidney.

### Toxicity

Zinc phosphide is an extremely toxic compound. The oral LD<sub>50</sub> in rats is 41 mg/kg body weight. In sheep, the LD<sub>50</sub> ranges from 60 to 70 mg/kg. It is also very toxic to cows, sheep, goats, pigs, rabbits, and other species. Following oral ingestion, both zinc phosphide and phosphine are absorbed from the GI tract, although the majority of acute effects are caused by phosphine. Zinc phosphide causes damage to the liver and kidney. Phosphine causes CNS depression, irritation of the lungs, and damage to the liver, kidney, heart, and CNS. Death occurs as a result of cardiac arrest or, more commonly, pulmonary edema. In addition, there are reports of cardiac arrest accompanied by kidney damage. Following a large dose, death usually occurs within 1 h, whereas with smaller doses, death can occur between 4 and 72 h. Symptoms usually appear 20–25 min after exposure. Animals are prostrated with deep slow respiration, finally terminating in convulsions. Following repeated exposure, cumulative effects occur in the liver, kidney, and lungs.

Zinc phosphide is highly toxic to wild animals and birds and to freshwater fish. The most sensitive bird species that have been evaluated are geese (LD<sub>50</sub> of 7.5 mg/kg). Pheasants, mourning doves, quails, mallard ducks, and horned larks are very sensitive to this rodenticide. The fish species that have been found sensitive to zinc phosphide include bluegill sunfish, rainbow trout, and carp.

### Diagnosis

Diagnosis of zinc phosphide in animals is based on detection of zinc phosphide, phosphine, and zinc in

body tissues and fluids. At necropsy, stomach content smells like acetylene. A zinc phosphide level of 50 ppm or higher in stomach content is considered significant and is indicative of zinc phosphide poisoning.

### Treatment

There is no specific antidote, and treatment is mainly symptomatic. Vomiting should be induced as soon as possible after ingestion, followed by the administration of activated charcoal. Sodium bicarbonate can be given orally to stop liberation of phosphine gas. Calcium gluconate and sodium lactate can be given intravenously to combat acidosis.

### Conclusion

Zinc phosphide is a slow-acting but highly toxic rodenticide. At acidic pH in stomach, zinc phosphide generates phosphine gas, which is responsible for the majority of toxic effects. There is no specific antidote, and treatment is symptomatic.

## THALLIUM

### Introduction

Thallium (Tl) is a bluish-white heavy metal that occurs naturally in the earth's crust. The word thallium derives from the Greek word *thallos*, which means a young twig or shoot. Tl enters the environment from natural and anthropogenic sources. Natural sources of Tl are less bioavailable and therefore of less toxicological concern than anthropogenic sources. The largest anthropogenic sources of Tl are related to coal combustion and heavy metal (primarily zinc and cadmium) smelting and refining. Tl salts were introduced as pesticides in Germany in 1920. The sulfate salt is most common and has been widely used as a rodenticide and ant killer. In the past, Tl was also used for medicinal purpose against dysentery with violent or persistent diarrhea, syphilis, gonorrhea, gout, mycosis of the scalp, and as an inhibitor of sweat secretion in tuberculosis patients. Approximately 50 years ago, Tl was frequently referred to as the poison of choice because Tl is as toxic as arsenic or lead. Tl is banned in many countries, but it is still widely available in developing countries as a rodenticide. The possibility also exists for Tl to be used as a chemical warfare agent (Thompson, 2009). In general, Tl poisoning cases are on the decline, but diagnostic labs still receive suspected baits and tissues from poisoned animals, especially dogs, on a regular basis.

## Background

Thallium is a toxic heavy metal that was discovered by Sir William Crookes in 1961 by burning the dust from a sulfuric acid industrial plant. It forms two kinds of compounds: monovalent thallo- and trivalent thalli- compounds. The monovalent Tl resembles potassium, and trivalent Tl resembles aluminum. Tl tends to form stable complexes with soft ligand donors, such as sulfur-containing compounds. Inorganic Tl (I) compounds are more stable than Tl (III) analogs in aqueous solution at neutral pH. In contrast, organothallium compounds are stable only in the trivalent form. Tl is particularly toxic in its Tl (I) compounds, such as sulfate ( $\text{Tl}_2\text{SO}_4$ ), acetate ( $\text{CH}_3\text{COOTl}$ ), and carbonate ( $\text{Tl}_2\text{CO}_3$ ). The sulfide ( $\text{Tl}_2\text{S}$ ) and iodide (Tl I) are both poorly soluble and therefore much less toxic. Today, Tl is recognized as one of the most toxic heavy metals, with an  $\text{LD}_{50}$  of 30 mg/kg in rats and 8–12 mg/kg in humans.

## Toxicokinetics

The water-soluble Tl compounds are rapidly absorbed following oral, inhalation, and dermal exposure. After absorption, Tl compounds are widely distributed to the body tissues, including brain, heart, kidney, skeletal muscle, and testes. Both monovalent and divalent Tl appear to distribute in tissues in a similar manner. In blood, Tl is found slightly more within erythrocytes than in plasma. Following an acute exposure, the maximal concentration of Tl is found in the kidneys, preferentially in the medulla. Studies conducted in rats show lower concentrations of Tl in renal tissue of young compared to adult.  $\text{Tl}^+$  and  $\text{K}^+$  are monovalent cations with similar ionic radii, but  $\text{Tl}^+$  accumulates intracellularly more than  $\text{K}^+$  because of its greater affinity for certain enzymes and protein. Because of its large volume of distribution and low free plasma concentration, renal excretion of Tl is slow, and its residue can be detected in the tissues for months. Organic Tl compounds, such as thallous malonate, show a higher elimination rate constant but are similar in toxicity and distribution pattern compared to the inorganic Tl compounds, such as thallous sulfate (Aoyama, 1989). The elimination half-life is between 8 and 30 days. Tl is excreted in urine, bile, feces, saliva, tears, and milk. In mammals, Tl excretion via the GI tract is twice that of the kidneys because of its involvement in enterohepatic circulation. Tl is known to pass in the milk of poisoned female rats, mice, guinea pigs, and humans. A significant fraction of free plasma Tl also crosses the placental barrier. A small amount of Tl can also be found in hair. Following chronic exposure, Tl can be deposited in the bones, which may account for its cumulative toxicity.

## Mechanism of action

Tl produces toxicity in mammals through multiple mechanisms.  $\text{Tl}^+$  and  $\text{K}^+$  have common cellular targets and receptor sites associated with biological activity and toxicity.  $\text{Tl}^+$  replaces  $\text{K}^+$  in the intracellular environment and shows a 10-fold greater affinity over  $\text{K}^+$  for  $\text{Na}^+/\text{K}^+$ -ATPase. Tl at higher concentrations competitively inhibits  $\text{Na}^+/\text{K}^+$ -ATPase activity. Mitochondria have an abundance of  $\text{Na}^+/\text{K}^+$ -ATPase and are particularly susceptible to the effects of Tl. Tl inhibits the influx and efflux of  $\text{K}^+$  in mitochondria, without causing any alterations in movement of  $\text{Na}^+$ . In addition, Tl inactivates sulfhydryl groups, including those affecting the permeability of the outer mitochondrial membrane. As a result of mitochondrial dysfunction, a variety of morphological changes, including mitochondrial swelling and vacuolization, occur in mitochondria in kidney, liver, brain, pancreas, and other tissues of mammals. Tl compromises mitochondrial energy production by inhibiting pyruvate dehydrogenase complex and succinate dehydrogenase by uncoupling oxidative phosphorylation. Tl is also known to disrupt normal cell metabolism by stimulating several  $\text{K}^+$ -dependent enzymes, such as phosphatase, homoserine dehydrogenase, vitamin  $\text{B}_{12}$ -dependent diol dehydrogenase, L-threonine dehydratase, and AMP deaminase.

Tl has been demonstrated to increase the levels of hydrogen peroxide and decrease the levels of glutathione, which leads to enhanced lipid peroxidation, oxidative stress, and energy depletion primarily in the brain (Hasan and Ali, 1981; Hanzel and Verstraeten, 2005). Tl-induced changes, such as cellular energy loss, depletion of flavoproteins, and binding of Tl to active sulfhydryl sites of enzymes, are the proposed mechanisms for Tl neuropathy. The complexing of Tl to cysteine appears to inhibit crosslinking of proteins and thereby causes inhibition of keratinization of hair. Tl blocks formation of the disulfide bonds in keratin and thus leads to hair loss (Mulkey and Oehme, 1993). Most evidence supports direct involvement of Tl with the hair follicles as the mechanism of hair loss.

## Toxicity

Tl toxicity has been studied extensively in rats, mice, guinea pigs, rabbits, dogs, and humans. In general, Tl compounds are extremely toxic to humans and animals. Tl has been classified as the most toxic cumulative metal cation. A single dose of 15 mg Tl/kg body weight has been found to be lethal in guinea pigs, dogs, and humans. The  $\text{LD}_{50}$  is 15 mg/kg in rats and 16–27 mg/kg in mice. Of course, these values vary depending on the form of Tl (Mulkey and Oehme, 1993).

Onset of signs and symptoms of Tl poisoning is slow (i.e., within 48h). The signs and symptoms of Tl toxicity (thallotoxicosis) can vary depending on the species, age, form of Tl, dose, and acute versus chronic exposure. Gastroenteritis, polyneuropathy, and hair loss are the dominant features of Tl poisoning (Mulkey and Oehme, 1993). Acutely poisoned animals show abdominal pain, vomiting, and constipation or diarrhea. At a high dose exposure, neurologic signs dominate with peripheral neuropathy. Sensory disturbances include pain, ataxia, and paresthesia, which progress to muscle atrophy. Muscle fibers can show myopathic changes with abnormal central nucleoli, striated transverse fibers disappearance, necrosis, and fibrosis. Cats dosed with Tl at 4 mg/kg body weight developed hypotonia and ataxia mainly due to pathological changes in sensory neurons (Sager, 1994). Dogs and cats exposed to Tl also showed hemorrhagic gastroenteritis and hepatic and renal damage.

Surviving animals usually show signs of alopecia, bloody lesions of the skin, tremors, neuropathy (involving both central and peripheral nervous systems), and paralysis of muscles. In addition, Tl causes structural and functional changes in heart and kidneys. Evidence from experimental animal studies suggests that the reproductive system is highly susceptible to Tl. Humans and animals accumulate Tl in testes, where morphological and biochemical changes occur. Tl is embryotoxic and teratogenic in chick embryo, causing achondroplasia, leg bone curvature, beak deformity, microcephaly, and decreased fetal size. However, teratological investigations in mammals have produced conflicting results (Gregotti and Faustman, 1998). For further details on Tl toxicity, refer to Mulkey and Oehme (1993) and Galvan-Arzate and Santamaria (1998).

### Diagnosis

Diagnosis of Tl poisoning is based on evidence of Tl exposure, clinical signs, and chemical confirmation in body tissue/fluid. Quantitative analysis for Tl in urine, serum, feces, saliva, or hair is performed to assess the extent of Tl exposure and to monitor treatment. Tl residue analysis at diagnostic labs is commonly carried out using atomic absorption spectrometer, inductively coupled plasma (ICP), or ICP-mass spectrometer-based methods. Tl-induced hematological changes may include anemia, leukocytosis, eosinophilia, and lymphocytopenia. Decreased creatinine clearance, elevated BUN, and proteinuria indicate renal function impairment. Alopecia is usually observed 3 or 4 weeks postexposure, thus diminishing the timely treatment.

### Treatment

Therapy for Tl poisoning should be instituted as early as possible. In the case of acute oral ingestion, supportive

care should include induction of vomiting followed by gastric lavage and use of laxatives to remove Tl as much as possible from the GI tract. Prussian blue (potassium ferric hexacyanoferrate (II)) is the treatment of choice for Tl exposure. Prussian blue acts by binding to Tl in the GI tract and makes it unavailable for absorption or reabsorption. Hemodialysis and hemoperfusion can be used to remove Tl from the circulation. At later stage of the treatment, potassium can be used to mobilize Tl from the tissues. Maintenance of vital organ functions should be a priority, especially in acute cases. If Tl poisoning is diagnosed and treated early, the chance for full recovery is good.

### Conclusion

Tl is one of the most toxic heavy metals used as a rodenticide. It produces a wide range of toxic effects involving multiple organs and mechanisms. Neurological, renal, and gastrointestinal effects are of primary concern. Exposure with a high dose is often fatal. Surviving animals often show complex signs of Tl poisoning, especially polyneuropathy, renal impairment, and hair loss. The diagnosis of Tl poisoning is based on clinical signs and Tl detection in urine, serum, or other biological tissue/fluids. Timely therapy with Prussian blue and supportive measures can lead to full recovery.

## Avitrol

Ramesh C. Gupta

## INTRODUCTION

Avitrol (4-aminopyridine) is a white, odorless, crystalline sand-like material that is readily soluble in water. It has a chemical formula of  $C_5H_6N_2$  with a molecular weight of 94.1. Its chemical structure is shown in [Figure 58.1](#).

4-Aminopyridine was developed by the Phillips Petroleum Company and marketed in 1963 as an avicide under the name “Avitrol.” It was also considered a bird repellent. Currently, it is a product of the Avitrol Corporation (Tulsa, OK, USA). Avitrol has many other names, including 4-AP, 4-pyridylamine, 4-pyridamine, and amino 4-pyridine. Avitrol is currently used to control the overpopulation of certain birds that are considered pest birds, including pigeons, red-winged blackbirds, blackbirds, cowbirds, grackles, sparrows, starlings, gulls, and crows.

Depending on the bird species to be controlled, the formulation can be prepared in grain/corn or bread. Avitrol is available in various formulations, such as grain baits (0.5, 1, and 3%) and powder concentrate or powder mix (25 and 25%). According to the U.S. Environmental Protection Agency (EPA), grain bait formulations of 4-aminopyridine are categorized in toxicity class III, whereas powder concentrate formulations are in toxicity class I. Avitrol is intended to make a few birds in the flock sick; that is, the sick birds thrash around and scare

off the other birds. In higher doses, avitrol can not only be toxic or lethal to birds but also be lethal to non-target species. The use of 4-AP in birds has been criticized by the Humane Society of the United States ([Brasted, 2008](#)). This chapter describes the toxicity of avitrol in birds, mammals, and fish.

## BACKGROUND

Scientists have been seeking an ideal way to control pest birds that destroy crops, feed/grain meant for livestock, and ruin the look of beautiful buildings and monuments. A number of chemicals have been investigated for their ability to repel birds ([Clark, 1998](#); [Dolbeer \*et al.\*, 1998](#); [Stevens and Clark, 1998](#)). Currently, avitrol is the most popular avicide that is registered at the EPA for the control of certain pest birds that feed on cattle feed lots, field corn, wheat, sorghum, sunflowers, peanuts, pecans, grain, feed processing plants, etc. Avitrol is also used to drive away birds from monuments, airports, warehouse premises, and other public buildings ([Thomson, 1991–1992](#)). Upon ingestion, avitrol causes utter vocalization and physical distress (i.e., hyperactivity) in certain birds, which acts as an area repellency to the remainder of the flock – a so-called “flock frightening syndrome” ([Spyker \*et al.\*, 1980](#); [Meister \*et al.\*, 1984](#)). Wildlife feeding on treated bait can also be killed. In recent years, the use of avitrol has been banned in many cities, including New York, San Francisco, and Boulder, Colorado, because of its toxicity to non-target species. Many field cases of avitrol poisoning have been reported in birds and domestic, wild,

FIGURE 58.1 Chemical structure of 4-aminopyridine.

and zoo animals (Schafer, 1972; Schafer *et al.*, 1974; Nelson *et al.*, 1976; Ray *et al.*, 1978; Spyker *et al.*, 1980; Frank *et al.*, 1981; Nicholson and Prejean, 1981; Smith and Lewis, 1988; Conover, 1994). Avitrol has also been involved in suicidal attempts (Pickett and Enns, 1996; Johnson and Morgan, 2006). During approximately the past decade, 4-AP has received much attention because of its extensive application as a pharmacological drug in neurodegenerative diseases (Davidson *et al.*, 1988; Pinter *et al.*, 1997; Jensen and Shi, 2003) and as experimental potassium channel blocker (Hu *et al.*, 2006), calcium channel activator (Wu *et al.*, 2009), and apoptosis inducer (Chin *et al.*, 1997).

## TOXICOKINETICS

Like other aminopyridines, 4-aminopyridine is rapidly absorbed from the gastrointestinal (GI) tract into circulation. The compound is readily metabolized in the liver, and metabolites are excreted in the urine. Approximately 90% of the administered dose, following intravenous (i.v.) or oral administration, excretes in the urine.

## MECHANISM OF ACTION

In acute toxicity, the central nervous system (CNS) is the target organ, whereas in chronic toxicity the CNS and liver are the target organs. 4-Aminopyridine blocks potassium ion channels and increases acetylcholine levels at the synapses and neuromuscular junctions (Rowan, 1985). This results in hyperactivity, convulsions, and seizures. In acute toxicity, birds and animals suffer immensely. Avitrol impairs the bird's nervous system, and as a result, birds become disoriented and exhibit erratic flight, tremors, and violent convulsions for hours before they finally succumb to death. Avitrol also causes excess methemoglobin formation. Methemoglobin is unable to carry oxygen to the tissues, thereby causing respiratory distress. Death ensues due to cardiac and respiratory arrest.

## TOXICITY

Avitrol is highly toxic to all species of birds. It is also toxic to mammals, humans, fish, and wildlife. The oral acute LD<sub>50</sub> values (expressed as mg/kg body weight) for avitrol are reported to be 10–12 for chickens, 8 for gulls, 3 for crows, 5.6 for pheasants, 15 for bobwhite quail, 8 for mourning dove, 3.8–4 for sparrows, 5–6 for starlings,

4–7 for pigeons, 9 for blackbirds, and 3.2 for boat-tailed grackle (NPCA, 1972). The oral acute LD<sub>50</sub> value in rats is 20 mg/kg (Meister *et al.*, 1984), and in dogs it is 3.7 mg/kg (NPCA, 1972). The dermal LD<sub>50</sub> of technical-grade 4-AP in rabbits is 326 mg/kg (NPCA, 1972). LC<sub>50</sub> values of 4-AP for coturnix quails, mourning doves, and mallard ducks are 447, 316, and 722 ppm, respectively.

Avitrol produces toxicity in birds in a dose-dependent manner; that is, birds exposed to a low dose exhibit utter distress calls, whereas with higher dose they become incapacitated and die. Birds exposed to avitrol usually show onset of signs within 5–15 min and signs of severe intoxication for a period of 30–60 min. Poisoned birds become disoriented and exhibit erratic flight. Eventually, they are unable to stand or sit in a sternal position, and they show tremors and convulsions for a brief period to hours (Conover, 1994). In a case report, Bischoff *et al.* (2001) described the primary signs of poisoning in crows as frequent vocalization, CNS abnormalities, and inability to fly or walk. “Downed” birds either die or recover within 1–15 h (NPCA, 1972). Birds intoxicated with avitrol that react and alarm a flock usually die.

Non-target species including mammals are equally sensitive to the toxicity of avitrol. In mammals, avitrol produces symptoms similar to those of epileptic seizures. Doses near the LD<sub>50</sub> exert a usual sequence of symptoms including hyperexcitability, salivation, tremors, muscle incoordination, and convulsions, and death results from cardiac and respiratory failure. Most of these symptoms are associated with hypercholinergic activity. In general, onset of signs occurs within 10–15 min and death occurs within 15 min to 4 h.

Predators such as raptors, foxes, hawks, cats, and dogs die from secondary poisoning after feeding on dead or dying birds. Secondary poisoning has also been found in endangered birds, including red-tailed hawks and peregrine falcons, as they died from ingesting the remains of pigeons and other birds poisoned with avitrol.

Dermal exposure to avitrol can lead to systemic intoxication or general overall poisoning. Very few chronic studies have been done, and no conclusive findings have been reported. Currently, studies are not available to suggest that avitrol has any potential for mutagenic, teratogenic, or carcinogenic activity.

In fish, avitrol has been found to be moderately toxic (EXTOXNET, 1996). Fish become increasingly sensitive with increased exposure. The LC<sub>50</sub> ranges from 4 mg/L (in soft water) to 2.43 mg/L (in hard water) in channel cat fish. The LC<sub>50</sub> ranges from 3.40 mg (in soft water) to 3.2 mg/L (in hard water) in bluegill.

In humans, avitrol is known to cause seizures. Exposed individuals exhibit weakness, diaphoresis, altered mental status, and hypertension. Other symptoms include thirst, nausea, dizziness, weakness, ataxia, tremors, dyspnea, and tonic-clonic convulsions. Avitrol

also produces metabolic acidosis, leukocytosis, and elevations of serum enzymes (glutamic oxaloacetic transaminase, lactate dehydrogenase, and alkaline phosphatase) as notable laboratory findings. Death occurs due to respiratory failure.

## Diagnosis

Diagnosis of avitrol poisoning is based on history of exposure; clinical signs; pathologic findings; and residue determination of 4-AP in crop, GI content, or tissues. The crop and GI content have the highest levels of 4-AP. Residues of 4-AP can be determined using liquid chromatography (Uges and Bouma, 1981) and may be confirmed by gas chromatography-mass spectrometry. Small residue can also be found in the liver, heart, muscle, kidney, brain, and lung. Residue of 4-AP can be determined by thin layer chromatography, high-performance liquid chromatography, or gas chromatography-mass spectrometry.

## TREATMENT

Pancuronium is a pharmacologic antidote and is recommended in severely poisoned human patients. Propranolol appears to block some of the cardiac toxicity (e.g., cardiac arrhythmias) of 4-aminopyridine. Seizures can be treated with diazepam (0.1 mg/kg, i.v.). In severe cases, phenobarbital or phenytoin can be given if there is no response to diazepam. In the case of avitrol ingestion, general symptomatic and supportive treatment includes emesis, gastric lavage, activated charcoal, and cathartic sodium thiosulfate. Bicarbonate should be added to the fluids to treat acidosis.

## CONCLUSIONS

Avitrol is commonly used to deter pest birds from roosting and nesting. The compound is toxic to all species of birds. It is also toxic to mammals, birds, and fish. Secondary poisoning is very common in non-target birds and dogs. Avitrol produces toxicity by affecting the CNS, and as a result, toxic signs include hyperactivity, convulsions, and seizures.

## ACKNOWLEDGMENTS

I thank Mrs. Robin B. Doss and Ms. Michelle A. Lasher for their assistance in the preparation of this chapter.

# Toxic gases

Rhian Cope

## INTRODUCTION

For the purposes of this chapter, a gas is defined as a state of matter consisting of particles that have neither a defined volume nor a defined shape at standard temperatures and pressures. A vapor represents the gas phase of components from substances that are either solid or liquid at standard temperatures and pressures. Although much of the toxicology of gases is applicable to the toxicology of vapors, the focus of this chapter is classical gas toxicology.

This chapter is divided into two sections: general principles and specific toxic gases. The general principles section covers basic gas toxicokinetics and basic dosimetric adjustments for human risk assessment. The specific toxic gases section covers specific toxic gases that are of veterinary significance as well as those to which veterinarians are likely to be exposed, including carbon monoxide, hydrogen sulfide, oxides of nitrogen (sil-

filler's disease), gaseous ammonia (including anhydrous ammonia), and smoke inhalation.

## GENERAL PRINCIPLES

### Toxicokinetics

#### *Absorption and distribution*

Depending on their physicochemical properties, gases can be absorbed throughout the respiratory tract with resultant site of first contact effects, systemic toxicity, or a combination of both. The driving force for the systemic (i.e., entry into the bloodstream) and tissue absorption of inhaled gases is diffusion down concentration gradients (Rozman and Klaassen, 2001; Witschi and Last, 2001; Renwick, 2008; Valentine and Kennedy, 2008). This can be described at a high level by a series of simplified toxicokinetic equilibria and related equilibrium constants ( $K$ ):

The absorption of a gas will continue until equilibria are established in the various compartments. Once the equilibria are established, no net absorption will occur unless there is loss from the system (i.e., metabolism), reaction with tissue molecules, or excretion through nonrespiratory pathways (e.g., renal excretion). It is critical to note that just because the equilibria have been established does not mean that the concentrations in the relevant compartments are all equal. Rather, once the equilibria are established, the concentration ratios between the various compartments will remain constant provided that saturation of the system does not occur – that is, the air:blood:tissue(s) concentration ratios remain constant.

Absorption of the gas will continue if “losses” from the system occur. If the substance is lost through metabolism, the rate of continued absorption once the equilibria have been established is effectively the rate of metabolism of the substance. This mass-balance relationship is essentially the basis of closed respirometry measures of oxygen consumption and metabolic rate (that were pioneered by Laplace and Lavoisier in the 1770s). If the substance is lost from the system solely through nonrespiratory excretion once the equilibria have been established, the rate of continued absorption is essentially equivalent to the rate of nonrespiratory excretion.

Also, if the concentration of the gas in the tissue(s) is higher than that in the respiratory airspaces, the net diffusive force will drive the movement of the gas from the tissue(s) into the air. An example is the excretion of carbon dioxide produced by aerobic metabolism in the tissues that is driven by simple diffusion. This is also the basis for the net excretion of a gas once exposure has ceased.

In normal circumstances, gas diffusion is not rate limiting for the systemic absorption for three basic reasons: (1) generally ionized, hydrophilic molecules that are apt to be diffusion limited across biological membranes have low volatility and thus their concentration in normal air is very low; (2) alveolar type I pneumocytes are very thin and are in intimate contact with the pulmonary capillaries, effectively resulting in extremely short diffusion distances; and (3) gases absorbed through the alveoli are rapidly removed by the blood (Rozman and Klaassen, 2001; Witschi and Last, 2001; Renwick, 2008; Valentine and Kennedy, 2008). There are two exceptions: (1) carbon monoxide absorption is diffusion limited (the basis for its use in the lung diffusion capacity test or determination of the DLCO which is referred to as the TLCO or transfer capacity in Europe), and (2) the presence of interstitial lung disease increases the pulmonary diffusion distances and results in diffusion-limited absorption for gases (notably oxygen).

In a broad sense, two innate substance characteristics affect the rate of establishment of the equilibrium

between the respiratory airspaces and the bloodstream: (1) whether or not uptake of the gas is perfusion limited and (2) whether or not the uptake of the gas is ventilation limited (Rozman and Klaassen, 2001; Witschi and Last, 2001; Renwick, 2008; Valentine and Kennedy, 2008). These characteristic factors are directly related to a physicochemical property of the relevant gas called the blood:gas partition coefficient. This is the solubility ratio for the chemical in gas phase and the chemical dissolved in blood at equilibrium. For substances with low blood:gas partition coefficients, the ability of blood to absorb the gas is rapidly saturated, and thus only a small amount of the gas in the respiratory tract is removed by blood during each circulation. In such circumstances, changes in respiratory rate and/or respiratory minute volume have relatively little effect on the rate of transfer of the gas from the respiratory system to the bloodstream. However, small changes in the rate of flow of blood through the respiratory tract (i.e., perfusion) have relatively large effects on the rate of transfer of the gas from the respiratory system to the blood; that is, increasing pulmonary perfusion results in more rapid removal of the gas from the site of equilibration (the alveolar membranes) and thus a more rapid rate of transfer of the gas from the respiratory system to the bloodstream. Thus, for gases with a low blood:gas partition coefficient, blood gas equilibration occurs relatively quickly (~8–21 min for relatively blood-insoluble gases), and the absorption of such gases is essentially perfusion limited. Perfusion-limited gases tend to be sparingly soluble in water, relatively lipophilic and hydrophobic, and have high octanol:water partition coefficients (Fiserova-Bergerova and Diaz, 1986). However, other factors, such as the affinity of the particular gas to protein and other elements in blood, may also significantly impact the blood:gas partition coefficient (Veltman *et al.*, 2009). Notably, alteration in the level of lipid components in the blood (particularly blood triglycerides) can significantly increase the blood:gas partition coefficient of lipophilic xenobiotics and thus affect their inhalation absorption kinetics (Lin *et al.*, 2002). Ingestion of a high-fat meal during or before inhalation may result in an increased absorbed dose of an inhaled lipophilic gas, as well as affect the rate of excretion by exhalation of such substances.

The alternate extreme is gases that are ventilation limited ((Rozman and Klaassen, 2001; Witschi and Last, 2001; Renwick, 2008; Valentine and Kennedy, 2008). Ventilation-limited gases are highly soluble in blood (they tend to be hydrophilic or, in rare cases, zwitterion-like) and often have low octanol:water partition coefficients (Fiserova-Bergerova and Diaz, 1986). Again, other factors, such as the affinity of the particular gas to protein and other elements in blood, may also significantly impact the blood:gas partition coefficient (Veltman *et al.*,

2009). The majority of a ventilation-limited gas present at the respiratory exchange site is removed during each respiratory cycle because of its high affinity for blood. Thus, relatively little of the material remains in the alveoli at the end of each breathing cycle, and replenishment of the gas in the gas-exchange regions is dependent on subsequent ventilation. In this situation, relatively small changes in respiratory minute volume can produce relatively large effects on the rate of transfer of the gas from the respiratory system to the blood. The rate of pulmonary blood perfusion has little effect on the rate of transfer of the gas from the respiratory system to the blood because virtually all of the gas is removed from the gas-exchange site during each circulation, and thus increasing the rate of blood flow through the lung during each circulation would not result in additional gas absorption. The time to blood:gas equilibration for gases that are ventilation limited is at least 1 h and often much longer (days or, in some cases, never).

Gases may also be absorbed in the upper respiratory tract, particularly the nasal cavity (Rozman and Klaassen, 2001; Witschi and Last, 2001; Renwick, 2008; Valentine and Kennedy, 2008; Morris and Buckpitt, 2009). In these cases, gases may be systemically reversibly absorbed via diffusion processes in which the blood:tissue:air partition equilibria (and associated coefficients) are important; alternatively, the gas may react with tissue macromolecules in the upper respiratory tract (including being metabolized). In general, gases that are absorbed in the upper respiratory tract tend to be highly soluble in aqueous solutions (particularly in the mucous lining of the upper respiratory tract), highly reactive (i.e., site of first contact toxicants), or both (Renwick, 2008). For these gases, the nasal cavity can be regarded as being analogous to a “gas scrubber” that prevents or limits the exposure of the deeper respiratory tract tissues. Again, in general, gases that are poorly water soluble are generally poorly absorbed in the upper respiratory tract. A further general rule is that relatively little gas absorption occurs in the conducting airways (anatomic dead space) areas of the respiratory tract.

## Metabolism

Metabolism of gases can occur locally in the respiratory tract or at other distant sites (discussed elsewhere in this book). As a generalization, biotransformation of gases within the respiratory tract primarily occurs at two main locations: within the epithelia of the nasal cavity and within the Clara cells of the lung (Bogdanffy *et al.*, 1986, 1987; Castranova *et al.*, 1988; Baron and Voigt, 1990; Bogdanffy, 1990; Keller *et al.*, 1990; Hukkanen *et al.*, 2002; Castell *et al.*, 2005). Phase I biotransformation also occurs to a lesser degree in type II pneumocytes and in pulmonary macrophages. The immunohistochemical distribution and biochemical activity of biotransformation enzymes in the rat nasal cavity are shown in Table 59.1. As can be seen from the table, biotransformation potential is predominantly located in the olfactory and respiratory epithelia of the nasal cavity. Whether or not metabolism in the olfactory or respiratory epithelium predominates depends on which enzymes are involved and, in some cases, the particular substrate. Although it is notable that both phase I and phase II biotransformation reactions can occur in the nasal cavity, it is also notable that the biotransformation capacity of the nasal cavity is also a prime source of local toxication of xenobiotics (Bogdanffy, 1997).

Numerous studies have demonstrated that Clara cells are a rich source of cytochrome P450-dependent mixed-function oxidases and a prime site for P450-mediated phase I metabolism and toxication in the lung (Devereux, 1984; Devereux *et al.*, 1985; Baron and Voigt, 1990; Hukkanen *et al.*, 2002; Castell *et al.*, 2005).

## Excretion of gases via the respiratory tract

Simple single phase (or single compartment excretion kinetics) excretion of inhaled gases through the respiratory tract is in many ways dependent on the same factors as gas absorption by inhalation. Gases with a high blood:gas partition coefficient tend to be excreted relatively slowly due to the relatively large amount of the gas dissolved in the blood volume and the high affinity

TABLE 59.1 Distribution of biotransformation enzymes in the rat nasal cavity

Tissue type	AldH	Carb	FdH	NBE	P450 red	P450	EH	GSHt	B $\alpha$ POH
Squamous epithelium	Low	No data	No data	Low	No data	No data	No data	No data	No data

Bowman's glands	Low		Present	High	Present	Present	Present	Present	Present

AldH, acetaldehyde dehydrogenase; Carb, carboxylesterase; FdH, formaldehyde dehydrogenase; NBE, alpha-naphthyl butyrate esterase; P450 red, NADPH-cytochrome P450 reductase; P450, cytochrome P450s; EH, epoxide hydrolase; GSHt, glutathione-S-transferases; B $\alpha$ POH, benzo(a)pyrene hydroxylase. Data from Bogdanffy *et al.* (1986, 1987, 1991), Bogdanffy (1990), Keller *et al.* (1990), Trela and Bogdanffy *et al.* (1991a,b), and Bogdanffy and Taylor (1993).

of the gas for blood relative to its affinity for air. Gases with a low blood:gas partition coefficient tend to be excreted relatively rapidly because of the relatively small amount present in the blood volume and the greater affinity of the gas for air than for blood. However, respiratory excretion of gases that have a high affinity for tissues, particularly adipose tissues, may be biphasic (have two compartment excretion kinetics). This is most commonly observed with lipophilic gases that have a low blood:gas partition coefficient. The initial phase of excretion is relatively rapid due to the fast removal of the gas from the blood during exhalation. This is followed by a slower phase as the gas slowly redistributes from the tissue (most often adipose tissues) into the bloodstream, from which it is subsequently removed by exhalation.

### Basic dosimetric adjustments for human risk assessment

For the purposes of risk assessment, absorption dose adjustment (from animal data to humans) – that is, calculation of the human equivalent concentration (HEC) – gases can be categorized into three general classes (U.S. EPA, 2009):

- Category 1 gases: These gases are highly water soluble and/or irreversibly reactive in the surface liquid/tissues of the extrathoracic and tracheobronchial regions of the respiratory tract. Examples include hydrogen fluoride, chlorine, and formaldehyde. The following equations are used for calculation of regional gas dose ratios (RGDRs) and HECs:

$$\text{HEC}_{\text{relevant region (extrathoracic or tracheobronchial or pulmonary regions)}} = \text{NOAEC}_{\text{animal}} (\text{mg}/\text{m}^3) \times \text{RGDR} \quad (2)$$

where RGDR is calculated by

$$\text{RGDR}_{\text{extrathoracic regions}} = \frac{\left( \frac{V_E}{SA_{ET}} \right)_{\text{Animal}}}{\left( \frac{V_E}{SA_{ET}} \right)_{\text{Human}}}$$

$$\text{RGDR}_{\text{tracheobronchial region}} = \frac{\left( \frac{V_E}{SA_{TB}} \right)_{\text{Animal}}}{\left( \frac{V_E}{SA_{TB}} \right)_{\text{Human}}}$$

$$\text{RGDR}_{\text{pulmonary region}} = \frac{\left( \frac{Q_{Alv}}{SA_{PU}} \right)_{\text{Animal}}}{\left( \frac{Q_{Alv}}{SA_{PU}} \right)_{\text{Human}}}$$

Definitions:

- HEC = human equivalent concentration at the extrathoracic site of action
- NOAEC<sub>Animal</sub> = no observable adverse effect concentration for extrathoracic effects or tracheobronchial effects (or a similar toxicological threshold or dose)
- RGDR = regional gas dose ratio
- V<sub>E</sub> = respiratory minute volume in mL/minute
- SA<sub>ET</sub> = surface area of the extrathoracic region in cm<sup>2</sup>
- SA<sub>TB</sub> = surface area of the tracheobronchial region in cm<sup>2</sup>
- SA<sub>PU</sub> = surface area of the pulmonary region in cm<sup>2</sup>
- Q<sub>Alv</sub> = alveolar ventilation rate mL/min which can be approximated by 0.6 × V<sub>E</sub>

Note: standard values for V<sub>E</sub>, SA<sub>ET</sub>, and SA<sub>TB</sub> can be found in the U.S. EPA 2009 reference and in Derelanko MJ and Hollingeer MA (2001) Handbook of Toxicology, Second Edition. CRC Press.

- Category 3 gases: These gases are relatively insoluble in water and are not reactive in the extrathoracic and tracheobronchial regions of the respiratory tract. These gases are not “scrubbed out” in the upper respiratory tract and conducting airways and thus penetrate into the deep pulmonary areas, where they are available for absorption into the systemic circulation. Examples include styrene and most of the common anesthetic gases and vapors. The following equations used for calculation of an RGDR and HECs:

$$\text{HEC}_{\text{systemic effects}} = \text{NOAEC}_{\text{animal}} (\text{mg}/\text{m}^3) \times \text{RGDR} \quad (3)$$

where RGDR is calculated by

$$\text{RGDR}_{\text{systemic, category 3}} = (H_{b/g})_{\text{Animal}} / (H_{b/g})_{\text{Human}}$$

where  $H_{b/g}$  is the blood:gas partition coefficient.

- Category 2 gases: These gases are moderately water soluble, rapidly and reversibly reactive, and/or moderately to slowly irreversibly metabolized within respiratory tissues. These intermediate gases have the potential for both sites of contact and systemic toxic effects. An example is sulfur dioxide.

Risk assessment methodologies also commonly use Haber’s law for dosimetric adjustments pertaining to the duration of exposure to a gas. Ernest Warren and Fritz Haber noted during their studies of the acute (exposure durations between 1 and 120 min) lethality effects of poison gases (specifically gas weapons in the case of Fritz Haber, notably phosgene, methylchloroformate, cyanide gas, chloroacetone, xylybromide, and chlorine) that exposure to a low concentration of a poisonous gas for a long time often had the same effect (death) as exposure to a high concentration for a short time. Generally, a simple

mathematical relationship applied:  $C \times t = k$ , where  $C$  is the concentration of the poisonous gas,  $t$  is the time of exposure, and  $k$  is a constant or “toxic load” (Haber, 1924; Lohs, 1990; Witschi, 1999, 2000). If different concentrations and times of exposure are used, this implies that  $C_1 \times t_1 = C_2 \times t_2$ . This relationship, in theory, can also be used to extrapolate concentration values between short-term and long-term exposures:

$$C_2 = \frac{C_1 \times t_1}{t_2} \quad (4)$$

In modern risk assessment, the ten Berge modification of Haber’s law is commonly used:  $C^n \times t = k$  (ten Berge *et al.*, 1986). The exponential  $n$  is a regression coefficient for the exposure concentration–exposure duration relationships for the relevant effect. In general, the value of  $n$  lies between 1 and 3. If suitable data are not available to derive  $n$ , a default value of  $n = 1$  is used for extrapolating from shorter to longer exposure durations and a default value of  $n = 3$  is used for extrapolating from longer to shorter exposure durations. Using the ten Berge modification, the Haber’s law equation becomes

$$C_2 = \frac{C_1^n \times t_1}{t_2} \quad (5)$$

However, note that there are many cases in which Haber’s law and the ten Berge modified Haber’s law do not accurately describe the dose–time relationships for the toxicological effects of gases. The use of these simple relationships may seriously over- or underestimate the degree of toxicological effects, particularly when there are large extrapolations in terms of the time of exposure (Weller *et al.*, 1999; Miller *et al.*, 2000; Hoyle *et al.*, 2010). High-quality data for the specific duration of exposure of interest are preferable to the use of Haber’s law or the ten Berge modification.

If the use of Haber’s law (ten Berge modification), respiratory absorption, and the relative volume of air inhaled per unit time are factored into the evaluation, the HEC equation for repeated inhalation exposure becomes

$$\begin{aligned} \text{HEC} = & \text{NOAEC}^n \text{Animal (mg/m}^3) \times \frac{\text{Hours of exposure per day}_{\text{Animal}}}{\text{Hours of exposure per day}_{\text{Human}}} \\ & \times \frac{\text{Days of exposure/week}_{\text{Animal}}}{\text{Days of exposure/week}_{\text{Human}}} \times \frac{\text{Inhaled volume per day}_{\text{Animal}}}{\text{Inhaled volume per day}_{\text{Human}}} \\ & \times \text{RGDR} \end{aligned}$$

where:

$n$  = ten Berge exponential factor;

Hours of exposure per day<sub>Animal</sub> is commonly 4 hours per day for a single acute dose study or 6 hours per day for a repeat dose study

Hours of exposure per day<sub>Human</sub> is commonly 8 hours per day for workers and 24 hours per day for the general population

Days of exposure per week<sub>Animal</sub> is commonly 5 days per week, but up to 7 days per week may be used in some cases

Days of exposure per week<sub>Human</sub> is commonly 5 days per week for workers and 7 days per week for the general population

Inhaled volume per day<sub>Animal</sub>: standard respiratory volumes for rats are 0.29 m<sup>3</sup>/kg for a 6 hour exposure/day, 0.38 m<sup>3</sup>/kg for an 8 hour exposure/day; and 1.15 m<sup>3</sup>/kg for a 24 hour/day exposure. Typically the 6 hour exposure/day value is used for most rat studies.

Inhaled volume per day<sub>Human</sub>:

standard respiratory volume for humans (sedentary) is 5 m<sup>3</sup> for a 70 kg person exposed for 6 hours

standard respiratory volume for humans (sedentary) is 6.7 m<sup>3</sup> for a 70 kg person exposed for 8 hours

standard respiratory volume for humans (sedentary) is 20 m<sup>3</sup> for a 70 kg person exposed for 24 hours

standard respiratory volume for a human worker (light activity) is 10 m<sup>3</sup> for a 70 kg person exposed for 8 hours

## SPECIFIC TOXIC GASES

### Carbon monoxide

#### Overview, uses, and sources of exposure

Carbon monoxide (CO) is colorless, odorless and virtually undetectable without the use of gas detection technologies, hence its reputation as a “silent killer” (Weaver, 2004). CO is ubiquitous and most commonly produced by incomplete hydrocarbon combustion. A component of CO poisoning is almost always present in cases of smoke inhalation injury (Alarie, 2002; Jones, 2003; Fitzgerald *et al.*, 2006). CO is also produced by the mixed function oxidase-mediated biotransformation of methylene chloride (dichloromethane), a common solvent component present in paint strippers and degreasers (Weaver, 2004). The combustion of methylene chloride produces phosgene. CO is also produced endogenously as a byproduct of erythropoiesis.

CO is a very common, high-mortality cause of human poisoning in the United States (Sadovnikoff *et al.*, 1992; Meredith, 1993; McGuigan, 1999; Hampson and Stock, 2006; Harduar-Morano and Watkins, 2011). Epidemics of CO poisoning in humans (and animals) are notoriously associated with the occurrence of storms, particularly when storms are accompanied by a loss of electrical power. Veterinarians, farm workers, and animals are at risk of exposure to CO in intensive animal production

units that are heated using hydrocarbon combustion devices. Both acute lethal and sublethal CO poisoning are well-known problems in intensive pig operations, particularly those relying on gas heating systems (Boller, 1976; Keller, 1976; Wood, 1979; Stuart and Oehme, 1982; Dominick and Carson, 1983; Morris *et al.*, 1985a,b; Pejsak *et al.*, 2008). CO in engine fumes may also reduce egg hatchability (Swarbrick, 1989).

CO has also been investigated as a veterinary euthanasia agent, and it may have some value when mass euthanasia of poultry is necessary (Moreland, 1974; Simonsen *et al.*, 1981; Chalifoux and Dallaire, 1983; Lambooy *et al.*, 1985; Enggaard Hansen *et al.*, 1991; Kingston *et al.*, 2005; Gerritzen *et al.*, 2006). However, there are substantial operator safety concerns with the use of CO for this purpose. CO treatment has also been used to improving the color of muscle foods (Hamling *et al.*, 2008; Mantilla *et al.*, 2008; Jeong and Claus, 2010, 2011). Again, strict safety standards are necessary to protect human workers in such circumstances.

### Toxic dose

At physiological equilibrium, an atmospheric CO level of 50ppm produces a carboxyhemoglobin (COHb) level of 8% in humans, which is the basis for the U.S. Occupational Safety and Health Administration PEL 8-h time-weighted average level of 50ppm (Weaver, 2004). Reduction in cognitive performance occurs in humans exposed to levels as low as 17ppm for 1.5–2.5h (COHb level of 2%). Situations that result in lower alveolar oxygen partial pressure (e.g., high altitudes), increased alveolar ventilation (e.g., higher metabolic rates and increased activity), pre-existing cardiovascular or cerebrovascular disease, cardiac insufficiency, increased affinity of hemoglobin (Hb) for CO (e.g., fetal Hb), and decrease blood oxygen carrying capacity will reduce the tolerance to CO (Weaver, 2004). CO exposure is a noted cause of angina in humans with pre-existing cardiovascular disease.

Exposure of pregnant sows to CO levels of 150–400ppm for 48–96h results in stillbirth rates of 6.7–80.0% (Dominick and Carson, 1983). The risk of stillbirth increases significantly when COHb concentration is greater than 23%. Notably, piglets that are born live in such circumstances usually have hypoxic ischemic leukoencephalopathy. There is evidence that preweaning pigs have some capacity to adapt to high air CO levels given that exposure to 200ppm of CO for the first 21 days of life has no adverse effect on any performance or behavioral characteristics in weanling pigs; however, exposure to 300ppm in such circumstances results in reduced growth and production performance (Morris *et al.*, 1985a,b). Perinatal exposure to 250ppm of CO resulting in a COHb level of approximately 20% produced detrimental effects in neonatal pigs.

### Toxicokinetics and toxicodynamics

CO is one of the few diffusion-limited gases during respiratory absorption. Despite this, CO is rapidly absorbed through the respiratory tract (Weaver, 2004). Approximately 85% of absorbed CO binds to Hb with an affinity approximately 200–300 times higher than that of oxygen. The remainder binds to myoglobin in muscle and to blood proteins. Very small amounts are metabolized to carbon dioxide, which is subsequently exhaled. CO is excreted primarily through the respiratory tract and has a whole body half-life ( $t_{1/2}$ ) of 3 or 4h in adult humans.

Treatment with 100% oxygen shortens the adult human CO  $t_{1/2}$  to approximately 30–126min, and treatment with hyperbaric oxygen further shortens this to 23min (Weaver, 2004). The human COHb  $t_{1/2}$  is much longer at 7h.

### Pathophysiology

The principal mode of action of CO is tissue hypoxia secondary to reduced blood oxygen carrying capacity (Weaver, 2004). Reduced blood oxygen carrying capacity occurs because of the preferential binding of CO rather than oxygen to Hb (the affinity of Hb for CO is approximately 200–300 times higher than that of oxygen). The presence of COHb also results in a left shift of the oxygen:Hb dissociation curve, further exacerbating tissue hypoxia. Organs and tissues with poorly developed anastomotic vessels and high metabolic rates (e.g., the heart and brain) are particularly susceptible. Venous blood, which has a high level of COHb, is described as being “cherry red” in color.

Myoglobin also has a higher affinity for CO compared with oxygen (Weaver, 2004). Cardiac myoglobin is particularly vulnerable to this effect, and the result is direct myocardial depression. CO–myoglobin is described as having a bright pink to red coloration. CO also binds to cytochrome oxidases *in vitro* although at lower affinity than oxygen. Thus, the *in vivo* relevance of this effect is uncertain. However, such metabolic effects may be important under conditions of tissue hypoxia.

CO produces substantial endovascular oxidative stress (Weaver, 2004). CO triggers the release of oxygen radicals from neutrophils and triggers nitric oxide release from platelets with the subsequent formation of peroxynitrate. CO also triggers brain neuronal apoptosis, particularly in the hippocampus, which contributes to the common amnesic effect of the gas.

### Vulnerable populations

Vulnerable populations include any life stage in which fetal Hb is present, pregnant individuals, and individuals with pre-existing cardiovascular disease (Weaver, 2004).

### *Clinical presentation*

The most common clinical presentation is that the animal is found either unconscious or dead following acute high-level exposure. Nonpigmented mucous membranes, nails, and skin may have “cherry red” color. Humans with CO poisoning have been described as looking “pink-cheeked and healthy” (Weaver, 2004). Unfortunately, cherry red coloration of the mucous membranes, skin, and nails is not a reliable diagnostic sign, and often “cherry red means dead.” When CO is used as a euthanasia agent in dogs, short periods of vocalization and agitation can occur, even when the animal is apparently unconscious (Chalifoux and Dallaire, 1983).

With nonlethal exposures, any body system, organ, or tissue can be affected (Weaver, 2004). Most commonly, clinical signs pertain to hypoxic central nervous system (CNS) damage and may include apparent weakness, fatigue, depression, transient loss of consciousness, and seizure disorders. Cardiovascular signs and effects usually pertain to the effects of reduced blood oxygen carrying capacity, tissue hypoxia, and direct effects on the myocardium and may include exercise intolerance, dyspnea, syncope, and cardiac arrhythmias. Other noted effects include retinal hemorrhage, hearing loss, rhabdomyolysis, peripheral neuropathies, vomiting, and nausea. Permanent CNS injury, particularly to the hippocampus, caudate nucleus, globus pallidus, and the substantia nigra bilaterally, as well as the cerebellum, cerebral cortex, and dorsal thalamus, can be expected in animals that survive significant CO poisoning (Kent *et al.*, 2010).

In pigs, the most common clinically observable effects are abortion storms, stillbirth, increases in perinatal mortality, and reduced neonatal growth rates (Wood, 1979; Dominick and Carson, 1983; Morris *et al.*, 1985a,b). Reduced hatching rates may be observed in poultry (Swarbrick, 1989). Critically, human workers in these facilities may also experience symptoms of CO poisoning, the most common of which are headache, nausea, dizziness, vomiting, and weakness.

### *Diagnostic testing*

Elevated blood COHb is the most definitive form of testing (Weaver, 2004). The presence of COHb cannot be determined by normal pulse oximetry because these instruments cannot discriminate between COHb and oxyhemoglobin. Pulse co-oximetry is necessary. The presence of fetal Hb may give falsely elevated COHb levels during pulse co-oximetry. Electrocardiography is recommended because of the likely presence of cardiac arrhythmias and myocardial damage. Computerized tomography (CT) and magnetic resonance imaging of the brain may reveal brain neurological injury (particularly in the globus pallidus and other basal ganglia and the hippocampus); however, CT images may be normal in the early stages of poisoning.

### *Postmortem findings*

Common gross lesions include cherry red discoloration of the subcutaneous tissues, muscle, blood, and viscera. Unlike with cyanide poisoning, the cherry red discoloration does not fade relatively quickly over time. Histopathology findings include focal leukoencephalomalacia and other lesions that resemble brain ischemic hypoxia, particularly in the basal ganglia (especially the globus pallidus), cerebral cortex, and cerebral white matter.

### *Treatment*

The immediate treatment priority is the prompt removal of the patient from the source of exposure. Rescuers need to take great care not to become casualties in such circumstances. The administration of 100% oxygen may be helpful because this reduces the CO  $t_{1/2}$ . Hyperbaric oxygen therapy may offer some additional benefits, but it is rarely available in veterinary practice (Stoller, 2007).

### *Prognosis*

The prognosis is often poor. Although few data are available from the veterinary literature, human data indicate that a high proportion of survivors develop long-term or permanent neurological, neurocognitive, and neuropsychiatric sequelae (Hampson *et al.*, 2001; Weaver, 2004; Hopkins and Woon, 2006; Tapeantong and Pongvarin, 2009).

### *Prevention*

The best form of prevention is the effective use of CO monitors and alarms in addition to well-adjusted heating equipment and good ventilation.

## **Hydrogen sulfide**

### *Overview, uses, and sources of exposure*

Note that polioencephalomalacia in ruminants due to excessive intakes of sulfur (which is converted to hydrogen sulfide by rumen microflora-mediated metabolism) is discussed in other chapters of this textbook. Within the veterinary context, hydrogen sulfide ( $H_2S$ ; “sewer gas,” “swamp gas,” “sour gas,” and “stink damp”) is most commonly encountered as a byproduct of the decomposition of sulfur-containing organic material, particularly with manure tanks, septic tanks, sludge pits, cesspools or settling ponds, or enclosed spaces containing decomposing feed (Caravati, 2004; Chou *et al.*, 2006).  $H_2S$  may also be produced when hydrochloric acid and/or sulfuric acid are used to clean drains or when wool, hair, and hides are burnt.  $H_2S$  is also a byproduct of petroleum refining, tanning, rubber vulcanizing, coal and gas production, and a number of other industrial processes.  $H_2S$  is colorless, heavier than

TABLE 59.2 Dose thresholds for hydrogen sulfide

Concentration (ppm)	Effect
0.02	Human odor threshold
10	Obvious unpleasant odor + mild eye irritation
20	U.S. OSHA PEL 15-min ceiling limit
50	Definite conjunctival irritation
50–100	Mild respiratory irritation
100	Olfactory fatigue
150–200	Olfactory nerve paralysis
250	Prolonged exposure results in pulmonary edema
300–500	Imminent threat to life plus pulmonary edema plus potentially apnea
500	30- to 60-min exposure results in excitement, staggering, unconsciousness, apnea, and respiratory failure
500–1000	Acts primarily as a systemic poison producing unconsciousness and death due to respiratory paralysis
700	Rapid unconsciousness and death if not rescued immediately
5000	Sudden death

Data from Beauchamp *et al.* (1984).

air (concentrates in low-lying areas), flammable, and explosive.

H<sub>2</sub>S is a common and important cause of sudden death in humans, and carries with it the mantra “one breath means death” (Caravati, 2004). Within the farm context, agitation of solutions containing dissolved H<sub>2</sub>S may greatly increase the level in air (Hooser *et al.*, 2000). This is of great importance in the case of manure tanks, septic tanks, sludge pits, and settling ponds. Exposure of confined cattle to H<sub>2</sub>S liberated by agitation of a manure pit has resulted in significant mortality. A very common cause of human casualties due to H<sub>2</sub>S poisoning involves misguided rescue attempts (referred to as the “H<sub>2</sub>S lemmings over the cliff phenomenon”).

**Toxic dose**

Relevant dose thresholds for H<sub>2</sub>S are summarized in Table 59.2. A critical point in the dose response is the onset of odor fatigue and paralysis of the olfactory nerves (Caravati, 2004). At this point, individuals can no longer readily detect that they are being exposed to H<sub>2</sub>S.

**Toxicokinetics and toxicodynamics**

H<sub>2</sub>S is rapidly absorbed through the lungs, although respiratory excretion is minimal (Caravati, 2004; Chou *et al.*, 2006). Metabolic detoxification to sulfate within

erythrocytes and hepatocyte mitochondria occurs relatively rapidly. Sulfate is primarily eliminated in urine. Approximately 85% of an acutely lethal dose is eliminated per hour.

**Pathophysiology**

The classical pathophysiology is essentially the same as that for cyanide poisoning (Reiffenstein *et al.*, 1992; Smith, 1997; Milby and Baselt, 1999; Albin, 2000; Caravati, 2004; Woodall *et al.*, 2005; Chou *et al.*, 2006; Khoshniat, 2008; Oesterhelweg and Puschel, 2008; Ballerino-Regan and Longmire, 2010). H<sub>2</sub>S binds to the ferric moiety of cytochrome *c* oxidase, thus disrupting the mitochondrial electron transport chain, resulting in blocking of cellular aerobic energy generation. Anaerobic metabolism then predominates, resulting in lactate accumulation and metabolic acidosis. At lower concentrations, H<sub>2</sub>S is an eye, mucous membrane, and respiratory irritant (Caravati, 2004). The respiratory effects of H<sub>2</sub>S (initial respiratory stimulation followed by apnea) are produced by direct central respiratory effects and/or by sulfide stimulation of the chemoreceptors of the carotid body, which results in initial respiratory hypocapnia followed by reflex apnea that may be sustained and/or lethal if significant hypocapnia is present (Beauchamp *et al.*, 1984). Death from H<sub>2</sub>S poisoning is usually due to respiratory arrest and hypoxia (Caravati, 2004). Individuals who survive the initial exposure may subsequently die from the effects of pulmonary edema.

**Vulnerable populations**

Fetuses and neonates are assumed to be more vulnerable than adults (Caravati, 2004).

**Clinical presentation**

The H<sub>2</sub>S knockdown or “one breath means death” phenomenon occurs with exposures greater than 750ppm and is characterized by sudden collapse, loss of consciousness, and apnea (Reiffenstein *et al.*, 1992; Smith, 1997; Milby and Baselt, 1999; Albin, 2000; Caravati, 2004; Woodall *et al.*, 2005; Chou *et al.*, 2006; Khoshniat, 2008; Oesterhelweg and Puschel, 2008; Ballerino-Regan and Longmire, 2010). Individuals may recover if exposure ceases, although permanent neurological damage is a common sequel. Acute respiratory distress due to pulmonary edema occurs following prolonged exposures to greater than 250ppm (Caravati, 2004). At lower levels of exposure, upper respiratory and ocular irritation effects may dominate the clinical picture. Reactive airway disease, bronchiolitis obliterans, and pulmonary interstitial fibrosis have been reported in humans with chronic irritant exposures. Cardiac arrhythmias, nausea, vomiting, diarrhea, and abdominal pain are also common.

### Diagnostic testing

Measurements of H<sub>2</sub>S metabolites such as sulfide and thiosulfate in whole blood and/or urine, as well as breathing zone air sampling/monitoring, are useful (Caravati, 2004).

### Postmortem findings

Greenish discoloration of gray matter, viscera, and bronchial secretions may be evident in fresh tissues, but the coloration is lost with formalin fixation (Park *et al.*, 2009). Fresh tissues may also have a distinctive sulfide smell and may undergo accelerated decomposition.

### Treatment

The immediate treatment priority is the prompt removal of the patient from the source of exposure (Reiffenstein *et al.*, 1992; Smith, 1997; Milby and Baselt, 1999; Albin, 2000; Caravati, 2004; Woodall *et al.*, 2005; Chou *et al.*, 2006; Khoshniat, 2008; Oesterhelweg and Puschel, 2008; Ballerino-Regan and Longmire, 2010). Rescuers need to take great care not to become casualties in such circumstances. The next treatment priority is resuscitation and provision of 100% oxygen (Caravati, 2004). Induction of methemoglobinemia by administration of nitrites, based on the predilection of sulfide to bind to ferric ions forming sulfmethemoglobin and thus potentially removing the sulfide from cytochrome oxidase and reactivating aerobic metabolism, has been suggested as an antidotal therapy. In clinical reality, nitrites are only effective if administered within seconds to minutes of exposure. Hydroxycobalamin has been proposed as an antidote for H<sub>2</sub>S poisoning on the basis that the pathophysiology resembles that of acute cyanide poisoning (Truong *et al.*, 2007; Fujita *et al.*, 2011). This antidote seems to have some effect under laboratory conditions. However, its effectiveness under field conditions has not been adequately investigated. Hyperbaric oxygen has also been proposed as being beneficial; however, it is rarely available in veterinary practice (Smilkstein *et al.*, 1985; Whitcraft *et al.*, 1985; Lindenmann *et al.*, 2010).

### Prognosis

The prognosis is variable depending on the duration of apnea and the degree of CNS hypoxia (Caravati, 2004). Some individuals appear to recover without any subsequent problems; however, a significant proportion of survivors will develop subsequent neurological problems associated with brain hypoxia.

### Prevention

Loss of detection ability (odor fatigue and/or olfactory nerve paralysis), ill-advised entries into closed spaces, and

misguided attempts to rescue casualties have all been associated with many deaths. The use of electronic exposure monitors (both personal and in spaces) and the immediate availability of personal protective equipment have saved many lives. Great care should be taken not to stir or agitate manure tanks, septic tanks, sludge pits, cesspools, or settling ponds. The use of hydrochloric acid and/or sulfuric acid-based drain cleaners should be avoided.

## Oxides of nitrogen (silo filler's disease)

### Overview, uses, and sources of exposure

The main gas involved is nitrogen dioxide (NO<sub>2</sub>), although other reactive oxides of nitrogen may also be present (Lowry and Schuman, 1956; Jonas, 1984; Pladson, 1984; Douglas *et al.*, 1989; Epler, 1989; Gurney *et al.*, 1991; Zwemer *et al.*, 1992; Leavey *et al.*, 2004). NO<sub>2</sub> has a bleach-like odor, a reddish-brown to yellow color, and leaves a yellow stain on silage, wood, or other contact materials. It is heavier than air. The most commonly encountered source in veterinary medicine is from silos that have been recently filled with fresh organic material (notably corn or other grains) or in silage pits. NO<sub>2</sub> is formed when nitric oxide in fresh silage or silo contents comes in contact with oxygen in the air. Silage gas also typically contains carbon dioxide. Silo gas has been a cause of mortality in dairy cattle (Haynes, 1963; Verhoeff *et al.*, 2007).

Toxic (and potentially lethal) levels of NO<sub>2</sub> can develop within hours on top of the material in the silo or silage pit (Groves and Ellwood, 1989). Within silos, the gas tends to seep down through the silo chute. The risk is highest when feedstuffs that are high in nitrates are ensiled or used for silage. Gas production typically peaks at approximately 24h, but it may last for several days. Other veterinary-relevant sources of NO<sub>2</sub> include kerosene heaters, unvented gas stoves and gas heaters, and tobacco smoke.

### Toxic dose

The U.S. EPA National Ambient Air Quality Standards lists 0.053ppm as the 24-h time-weighted average upper limit for NO<sub>2</sub> in air. Levels of 25.9ppb (SD, 18.1ppb) are known to increase the risk of pediatric asthma in humans (Belanger *et al.*, 2006). Brief exposures to 200ppm can be fatal, and exposure to 50ppm can result in significant pulmonary edema. A 1-h exposure to 1ppm is associated with deleterious effects in the lung. The human odor threshold is approximately 0.1–0.2ppm.

### Toxicokinetics and toxicodynamics

NO<sub>2</sub> is relatively water insoluble, and accumulation in the upper respiratory tract is limited (Jonas, 1984; Douglas

*et al.*, 1989; Epler, 1989; Gurney *et al.*, 1991; Leavey *et al.*, 2004). The high levels of carbon dioxide present in silage gas may stimulate deeper inspiration of the gas, resulting in a higher delivered dose in the deep lung.

### **Pathophysiology**

NO<sub>2</sub> dissolves in water to produce nitrous and nitric acids, which are irritant and corrosive (Jonas, 1984; Douglas *et al.*, 1989; Epler, 1989; Gurney *et al.*, 1991; Leavey *et al.*, 2004). Free radical generation and associated damage are also an important part of the pathophysiology. The acids are also immunosuppressive and result in a reduced resistance to infection. With prolonged or high levels of exposure, NO<sub>2</sub> is absorbed. Absorbed NO<sub>2</sub> binds with high affinity to hemoglobin, forming nitrosyl hemoglobin, which is further oxidized to methemoglobin. Methemoglobinemia produces a left shift of the hemoglobin:oxygen disassociation curve, further impairing tissue oxygen delivery.

### **Vulnerable populations**

Individuals with pre-existing reactive airway disorders, asthma, and lung disease are likely to be at greater risk.

### **Clinical presentation**

Clinical disease is associated most with harvest season. The clinical presentation depends on the concentration and duration of exposure (Jonas, 1984; Pladson, 1984; Douglas *et al.*, 1989; Epler, 1989; Gurney *et al.*, 1991; do Pico, 1992; Zwemer *et al.*, 1992; Stepanek *et al.*, 1998; Leavey *et al.*, 2004). High levels can produce sudden death due to bronchiolar spasm, laryngeal spasm, reflex respiratory arrest, and/or asphyxia. Lower exposures may be asymptomatic, mild, and self-limiting or result in eye irritation, pulmonary edema, and/or acute respiratory distress syndromes. Mucous membrane irritation is uncommon because NO<sub>2</sub> does not tend to dissolve onto wet mucous membrane surfaces.

Failure to adequately treat significant NO<sub>2</sub> exposure with corticosteroids results in bronchiolitis obliterans, particularly in the small airways and alveolar ducts, and permanent restrictive lung disease. Bronchiolitis obliterans can develop weeks or months following the initial exposure.

### **Diagnostic testing**

Apart from air sampling/monitoring, there are no specific diagnostic tests.

### **Postmortem findings**

Chemical pneumonitis and pulmonary edema primarily located in the deep lung are the predominant findings.

Emphysema may be present, depending on the duration of the toxidrome. Typically, type I pneumocytes, pulmonary mast cells, and ciliated airway cells are the most affected cell types.

### **Treatment**

The immediate treatment priority is the prompt removal of the patient from the source of exposure. Rescuers need to take great care not to become casualties in such circumstances. The next treatment priority is the administration of 100% oxygen and resuscitation. Pulmonary edema may develop up to 48h following exposure, so volume expanders and fluid therapy must be used with great caution during this period. Corticosteroids are important for reducing the risk of bronchiolitis obliterans. The use of broad-spectrum antibiotics with the objective of preventing bronchopneumonia may be justified. Subsequent follow-up management of reactive airway syndromes and asthma may be required.

### **Prognosis**

The prognosis depends entirely on the degree of lung damage and whether or not bronchiolitis obliterans and restrictive lung disease develop (Jonas, 1984; Douglas *et al.*, 1989; Epler, 1989; Gurney *et al.*, 1991; Zwemer *et al.*, 1992; Leavey *et al.*, 2004). In many cases, the toxidrome is mild and self-limiting; however, it may take months for pulmonary function to return to normal. Permanent mild loss of pulmonary function is relatively common.

### **Prevention**

The following methods can prevent exposure: stay out of silos during the 2-week danger period after the initial filling; close all silo doors before filling; use outside ladders rather than internal ladders in silos; if the silo is not completely full, remove the doors that lead down to the silage; enter the silo only with a complete oxygen support system; ventilate the silo by opening the cover flaps and running the silo blower for 24–48h before entering; never enter the silo alone or without a lifeline for rescue during the danger period; use a personal air monitor; and install air monitors in areas where NO<sub>2</sub> is likely to concentrate.

## **Gaseous ammonia**

### **Overview, uses, and sources of exposure**

Within the veterinary context, ammonia (NH<sub>3</sub>) is most commonly encountered anywhere decaying organic matter is present, particularly urine and feces (Roney *et al.*, 2004). In this context, it is ubiquitous within intensive animal production facilities. Swine and poultry production facilities are notorious for containing toxic levels of

TABLE 59.3 Dose thresholds for gaseous ammonia

Concentration (ppm)	Effect
≤25	8-h time weighted average human exposure limit
25–50	Detectable odor; unlikely to experience adverse effects
50–100	Mild eye and upper respiratory tract irritation; may develop tolerance in 1 or 2 weeks with no adverse effects thereafter
140	Moderate eye irritation; no long-term sequelae in exposures of less than 2 h
400	Moderate throat irritation
500	Immediately dangerous to life and health (human)
700	Immediate eye injury
1000	Severe airway injury
1700	Immediate laryngospasm
2500–6500	Sloughing and necrosis of airway mucosa, chest pain, acute lung injury, and bronchospasm
5000	Rapidly fatal

Data from Roney *et al.* (2004).

ammonia that are often higher than acceptable human threshold limit values (Sigurdarson *et al.*, 2004; Davis and Morishita, 2005; McDonnell *et al.*, 2008). Ammonia is lighter than air and will thus tend to rise from manure pits (Roney *et al.*, 2004). Ammonia is still used as a refrigerant, and leaks in such systems remain a common cause of serious incidents. The burning of nylon, silk, wood, and melamine also results in considerable production of  $\text{NH}_3$ .  $\text{NH}_3$  is a major component of many common household cleaning and bleaching products, and the mixing of these products with those that contain chlorine results in the liberation of chloramines, which are highly irritant and potentially dangerous (Pascuzzi and Storrow, 1998).

High-pressure anhydrous ammonia gas is a commonly used fertilizer in some locations because it is often the cheapest source of nitrogen. Errors in handling and leakage represent a substantial risk (George *et al.*, 2000; Fitzgerald *et al.*, 2006; Welch, 2006).

Anhydrous ammonia is an important component in the manufacture of methamphetamines (Bloom *et al.*, 2008). Theft of anhydrous ammonia from farms has become commonplace and has resulted in numerous serious incidents (Amshel *et al.*, 2000; Latenser and Lucktong, 2000; Lessenger, 2004; Welch, 2006). Due to the unique chemical properties of anhydrous ammonia, it can exert extremely high pressures even at relatively low temperatures; thus, specialized containers and equipment are required for safe handling of the gas. Attempts at anhydrous ammonia theft often involve the use of propane tanks that are not designed to handle the physicochemical properties of

anhydrous ammonia, and the risk of explosion of these types of containers is high. Veterinarians and farmers should be extremely cautious around apparently empty propane tanks that have blue- or green-discolored valves or if the tanks have frost on them. Anhydrous ammonia may have been inappropriately stored in the container, and the container's brass, copper, or galvanized valve fittings may be compromised.

Liquid anhydrous ammonia expands to many times its original volume when released into air and forms large, highly dangerous vapor clouds. Aerosolized liquid anhydrous ammonia may behave as a dense gas and accumulate in low-lying spaces, even though it is normally lighter than air.

### Toxic dose

The concentration of  $\text{NH}_3$  in well-ventilated animal production facilities should remain below 30 ppm. The human odor threshold is approximately 10 ppm. The human dose response to  $\text{NH}_3$  is shown in Table 59.3. Adverse effects occur at concentrations greater than approximately 75 ppm. Anhydrous ammonia has an 8-h time-weighted average maximum acceptable exposure of 25 ppm, a short-term exposure limit of 35 ppm, and an immediately dangerous to life and health level of 500 ppm.

### Toxicokinetics and toxicodynamics

$\text{NH}_3$  is highly water soluble and thus tends to primarily affect the upper respiratory tract, mucous membranes, and the eye (Close *et al.*, 1980; O'Kane, 1983; Robinson *et al.*, 1990; Chao and Lo, 1996; Brautbar *et al.*, 2003; Makarovsky *et al.*, 2008). However, deeper structures may be affected if the upper respiratory tract "sink" is overwhelmed.

### Pathophysiology

$\text{NH}_3$  is irritant and/or corrosive depending on the concentration.  $\text{NH}_3$  reacts with tissue water to produce ammonium hydroxide, a strong alkali (Close *et al.*, 1980; Robinson *et al.*, 1990; Chao *et al.*, 1996; Brautbar *et al.*, 2003; Makarovsky *et al.*, 2008). The reaction is exothermic and capable of producing significant tissue burns. Ammonium hydroxide produces typical alkaline liquefaction necrosis. Alkali liquefaction necrosis results in deeper tissue damage than that caused by an equipotent acid. In addition, ammonium hydroxide tissue breakdown liberates water, aiding the further conversion of  $\text{NH}_3$  to ammonium hydroxide. Mild exposure primarily affects the upper respiratory tract and eyes, whereas more severe exposure may affect the entire respiratory tract. The degree of damage to the respiratory tract is dependent on the depth of inhalation, duration of exposure, concentration, and the pH change of the tissue fluids. Even mild levels of exposure can reduce pulmonary

clearance and potentially increase the risk of infections of the respiratory tract. Within animal facilities, ammonia is generally adsorbed by dust particles, which enable deeper penetration of the lung compared with gaseous  $\text{NH}_3$  (Kim *et al.*, 2008). In such circumstances, the toxicological thresholds for adverse effects may be lower than for gaseous  $\text{NH}_3$ .

Liquid anhydrous ammonia ( $-33^\circ\text{C}$ ) freezes tissue on contact and can produce deep, irreversible skin damage (Amshel *et al.*, 2000; Latenser and Lucktong, 2000; Lessenger, 2004; Welch, 2006).

### **Vulnerable populations**

Individuals with pre-existing lung disease, reactive airway syndromes, and/or asthma are at significantly greater risk.

### **Clinical presentation**

Clinical signs associated with relatively low-level exposures pertain to eye and upper respiratory tract irritation: shallow breathing, excessive lacrimation, nasal discharge, keratoconjunctivitis, corneal opacity, atrophic rhinitis, dyspnea, hemoptysis, hoarse voice, dysphagia, reduced production, and possibly increased rates of respiratory infections. Higher exposures can result in severe pulmonary disease and possibly acute respiratory distress.

### **Diagnostic testing**

Air monitoring is the most effective form of diagnostic testing.

### **Postmortem findings**

Irritation and possibly corrosion of the respiratory tract, particularly the upper tract, and exposed surfaces of the eye dominate the gross findings. Histological findings may include hyperplasia of the bronchiolar and alveolar epithelium.

### **Treatment**

The immediate treatment priority is the prompt removal of the patient from the source of exposure. Rescuers need to take great care not to become casualties in such circumstances. Copious skin and eye irrigation should be performed for at least 20 min (taking care to avoid hypothermia). Patients should then be treated for acute respiratory distress and/or burns. In animal production facilities, the best treatment is to improve ventilation and to reduce the accumulation of animal wastes within the facilities.

### **Prognosis**

The prognosis depends on the severity, depth, and chronicity of respiratory tract injury. Reactive airway diseases and

asthma are common following  $\text{NH}_3$  exposures. Chronic respiratory sequelae may occur with severe exposures.

### **Prevention**

Improved ventilation and removal of wastes is the most effective form of prevention within intensive animal facilities. The use of air monitors (personal and space) and personal protective equipment has reduced human casualties. Veterinarians and farmers should have a very high degree of suspicion regarding areas where high levels of  $\text{NH}_3$  might be present, particularly enclosed spaces. Improved security of liquid anhydrous ammonia storage facilities has been recommended.

## **Smoke inhalation**

### **Overview, uses, and sources of exposure**

Smoke inhalation injury results from a combination of exposure to gaseous combustion products, particulate matter (which may be superheated), and superheated air (Lee-Chiong, 1999; Alarie, 2002; Enkhbaatar and Traber, 2004; Fitzgerald *et al.*, 2006; Lee and Mellins, 2006; Schnepf, 2006; Sicoutris and Holmes, 2006; Stefanidou *et al.*, 2008). Thus, the syndrome results from a combination of thermal, gas, and particle effects. Smoke inhalation always involves some degree of carbon monoxide and cyanide poisoning. Combustion of plastics, polyurethane, wool, silk, nylon, nitriles, rubber, and paper leads to the production of cyanide gas. Other combustion products may include acrolein and other reactive aldehydes (organic combustion) and also chlorine, ammonia, ketones, hydrocarbons, and various acids (combustion of rubber and plastics).

### **Toxic dose**

The toxic dose depends on the source.

### **Pathophysiology**

Thermal damage primarily occurs in the upper respiratory tract, particularly in the oropharyngeal area, due to the poor heat conductivity of air and high dissipation of heat in the upper airways (Clark *et al.*, 1989, 1990; Clark, 1992; Lee-Chiong, 1999; Alarie, 2002; Enkhbaatar and Traber, 2004; Fitzgerald *et al.*, 2006; Lee and Mellins, 2006; Schnepf, 2006; Sicoutris and Holmes, 2006; Stefanidou *et al.*, 2008). Both pulmonary irritation and systemic effects occur. Systemic effects occur primarily due to direct and chemical asphyxiation. Chemical asphyxiation most commonly occurs as a result of a combination of carbon monoxide and cyanide poisoning. Methemoglobinemia occurs due to direct heat denaturation of hemoglobin, as well as the inhalation of nitrites.

### Vulnerable populations

Individuals with pre-existing lung disease, reactive airway syndromes, and/or asthma are at significantly greater risk.

### Clinical presentation

Any individual with facial burns is likely also to have concurrent smoke inhalation injury. Individuals who no longer have eyelashes are very likely to have concurrent ocular injury. Common early clinical signs of respiratory tract injury include hoarseness and a change in voice, carbonaceous nasal discharge or sputum, coughing, tachypnea, and use of accessory respiratory muscles (Clark *et al.*, 1989, 1990; Clark, 1992; Lee-Chiong, 1999; Alarie, 2002; Enkhbaatar and Traber, 2004; Fitzgerald and Flood, 2006; Lee and Millens, 2006; Schnepp, 2006; Sicoutris and Holmes, 2006; Stefanidou *et al.*, 2008). Later clinical signs are related to progressive pulmonary decline and acute respiratory distress.

### Diagnostic testing

Bronchoscopy is the definitive diagnostic procedure. Clinical chemistry may indicate metabolic acidosis resulting from a combination of hypoxia, CO poisoning, cyanide poisoning, and methemoglobinemia. Elevated serum lactate is a relatively sensitive indication of cyanide poisoning. Patients may have lowered blood cholinesterases because the pyrolysis products of many phosphorus-based fire retardants are anticholinesterases. Pulse oximetry may provide misleading information due to the presence of COHb and methemoglobinemia. If available, pulse co-oximetry is preferable.

Chest radiographs are commonly normal after smoke inhalation, and the diagnostic accuracy of the technique is low. Chest computerized tomography (CCT) is a preferable imaging technique. CCT abnormalities include ground-glass opacities in a peribronchial distribution and/or patchy peribronchial consolidations. Such abnormal CCT findings may be present within a few hours following smoke inhalation. Pulmonary function tests are sensitive indicators of smoke inhalation injury, but they are rarely readily available in veterinary practice.

### Treatment

The immediate treatment priority is the prompt removal of the patient from the source of exposure. Rescuers need to take great care not to become casualties in such circumstances. The next treatment priority is the administration of 100% oxygen, resuscitation, and maintenance of airway patency (Clark *et al.*, 1989, 1990; Clark, 1992).

Unfortunately, there is no specific treatment for the tissue damage and increased risk of infection associated

with smoke inhalation. Studies in humans have indicated that positive pressure ventilation with low tidal volumes (3–5 mL/kg) and positive end-expiratory pressure may increase short-term survival (Cancio, 2009). High-frequency percussive ventilation, whole-body hypothermia, and hyperbaric oxygen may also decrease mortality (Reper *et al.*, 1998; Thom *et al.*, 2001). Unfortunately, none of these techniques are readily available in veterinary medicine. Induction of methemoglobinemia for the treatment of cyanide poisoning may be dangerous if significant CO poisoning is also present. However, the use of hydroxocobalamin (Cyanokit) in combination with low-dose sodium thiosulfate as a cyanide antidote may be considered (Borron *et al.*, 2007a,b). Bronchodilator therapy is almost always indicated in cases of smoke inhalation.

Patients with significant smoke inhalation commonly require concurrent treatment for burns, a subject that is beyond the scope of this chapter.

### Prognosis

The prognosis is entirely dependent on the degree of smoke injury and associated injury. Significant smoke inhalation always has a guarded prognosis.

# Alcohols and glycols

Mary Anna Thrall and Dwayne W. Hamar

## INTRODUCTION

Alcohols comprise a class of organic compounds composed of a hydrocarbon chain and a hydroxyl group. Alcohols that have one hydroxyl group are called monohydric, which include methanol, ethanol, and isopropanol, which are the three alcohols most commonly responsible for alcohol toxicosis. Alcohols are also classified as primary, secondary, or tertiary, according to the number of carbon atoms bonded to the carbon atom to which the hydroxyl group is bonded. Ethanol and methanol are primary alcohols, and isopropanol is a secondary alcohol. Glycols have two hydroxyl groups in their molecules and are dihydric. Ethylene glycol (EG) is the most common glycol responsible for poisonings, and EG poisoning is significantly more common in domestic animals than is alcohol toxicosis. Propylene glycol and butylene glycol are much less toxic than EG.

Alcohols and glycols are initially metabolized by hepatic alcohol dehydrogenase (ADH). Toxicosis from alcohols and glycols results in central nervous system (CNS) depression, ranging from decreased motor function to decreased consciousness, hypothermia, hypotension, coma and death from respiratory depression, and cardiovascular collapse. However, metabolites of the alcohols and glycols vary greatly in their toxicity. Metabolites of EG are nephrotoxic and result in acute renal failure. In primates, metabolites of methanol may result in blindness and permanent neurologic abnormalities.

## BACKGROUND

Reports of alcohol toxicosis are relatively quite rare in domestic animals compared to the reported incidence

in human beings. Ethanol, methanol, and isopropanol poisoning are all quite common in humans. Methanol and isopropanol are usually ingested by adults as a substitute for ethanol or in an attempt to commit suicide. In children, ingestion is usually accidental. Propylene glycol toxicosis is relatively rare in both humans and domestic animals. Butylene glycol toxicosis is also rare, but the incidence in humans has increased recently as it is regarded as a neuromodulatory “recreational” drug (Irwin, 1996). EG toxicosis is relatively common, both in humans and in domestic animals (Barton and Oehme, 1981; Mueller, 1982; Rowland, 1987; Hornfeldt and Murphy, 1998). In humans, it is ingested either accidentally, as a substitute for ethanol, or to commit suicide; approximately 5000 episodes are reported in the United States each year (Litovitz *et al.*, 1997). The vast majority of these poisonings are unintentional, and approximately one-third of the cases occur in children (Litovitz *et al.*, 1997). EG is the most common cause of human poisoning in some countries, such as Poland (Sienkiewicz and Kwiecinski, 1992).

Most incidents of EG toxicosis in domestic animals are also accidental, although malicious poisonings also occur. The mortality rate in dogs is reported to range from 50 to 70% (Barton and Oehme, 1981; Rowland, 1987; Connally *et al.*, 1996), and it is likely even higher in cats. EG intoxication is the second most common cause of fatal poisoning in animals, according to the American Association of Poison Control Centers (Hornfeldt and Murphy, 1998).

The first reported case of EG intoxication in a human occurred in 1930 (Anonymous, 1930), but the toxicity of EG was not fully realized until 1938 when 76 people died after consuming an elixir of sulfanilamide containing 96% diethylene glycol (Geiling and Cannon, 1938). Since then, many reports of EG poisoning in humans and animals have been published.

## ALCOHOL TOXICOSES

### Ethanol toxicosis

Ethanol (ethyl alcohol) has the structural formula  $C_2H_5OH$ , a molecular weight of 46 Da, and is the alcohol in alcoholic beverages. The percentage of ethanol in alcoholic beverages is one-half of the drink's proof value. It is also used in perfumes and mouthwashes. Ethanol toxicosis in dogs has been associated with ingestion of bread dough (Thrall *et al.*, 1984a; Suter, 1992; Means, 2003). Uncooked bread dough contains *Saccharomyces cerevisiae* (common brewer's and baker's yeast), which metabolizes carbohydrate substrates to ethanol and carbon dioxide. Ethanol poisoning in dogs has also been associated with rotten apples (Kammerer *et al.*, 2001) and alcoholic beverages (van Wuijckhuise and Cremers, 2003). Ethanol toxicosis can also occur in dogs and cats when ethanol is given intravenously (i.v.) as a competitive substrate to treat EG toxicosis. In a study in which cats were experimentally poisoned with EG and then treated with intraperitoneal (i.p.) ethanol at a dose of 5 mL of 20% ethanol/kg body weight every 6 h, serum ethanol concentrations ranged from as low as 16 mg/dL at 6 h post-i.p. ethanol to as high as 240 mg/dL 30 min post-i.p. ethanol. Cats with serum ethanol concentrations of more than 200 mg/dL appeared to be near respiratory arrest and were hypothermic (Thrall *et al.*, 1988).

### Toxicokinetics

Ethanol is rapidly absorbed from the gastrointestinal (GI) tract; the rate of absorption can be slowed by the presence of food in the stomach or small intestine. Clinical findings in dogs and cats with ethanol intoxication can be correlated with blood ethanol concentration (BEC). Clinical signs include ataxia, lethargy, sedation, hypothermia, and metabolic acidosis. Time of onset of clinical signs is dependent on the dose ingested and the amount of food present in the GI tract, but it usually occurs within an hour of ingestion. Although respiratory depression usually develops when the concentration is between 400 and 500 mg/dL, death has been reported in a human being with BEC as low as 260 mg/dL (Maling, 1970).

### Mechanism of action

The mechanism of action of alcohol on the CNS is related in part to its interactions with biomembranes and its probable inhibition of gamma-aminobutyric acid receptors (Valentine, 1990).

### Diagnosis and treatment

A diagnosis can be made based on history, clinical signs, increased plasma osmolality and osmole gap, metabolic

acidosis, and BEC, which can be measured by most laboratories. Hyperosmolality as a result of alcohol toxicosis must be determined using a freezing-point depression osmometer because vapor pressure osmometers do not detect the osmotic effects of alcohols (Champion *et al.*, 1975). It is important to differentiate EG toxicosis from alcohol toxicosis. The clinical signs and early laboratory findings can be similar. However, patients with EG toxicosis must be given ADH inhibitors such as 4-methylpyrazole to prevent the formation of toxic metabolites, whereas patients with ethanol toxicosis can be treated supportively. Severe ethanol intoxication usually requires mechanical ventilation using a cuffed endotracheal tube. Hypothermia may develop, and alterations in hydration, electrolyte, and acid-base status should be corrected (Richardson, 2006).

### Methanol toxicosis

Methanol (methyl alcohol and wood alcohol) has the molecular structure  $CH_3OH$ ; a molecular weight of 32 Da; and is widely used as a solvent, fuel (Sterno), gasoline additive, antifreeze, and windshield washer fluid (30–40% methanol). The minimum lethal dose in dogs is between 5.0 and 11.25 mL/kg, and in human beings it is 1.25 mL/kg (Valentine, 1990). Methanol toxicosis is rare in dogs, but it has been reported in a dog that chewed open a bottle of 98% methanol antifreeze (Hurd-Kuenzi, 1983).

### Toxicokinetics

Ingested methanol is absorbed quickly from the GI tract, and peak methanol concentrations occur within 30–60 min following ingestion (Barceloux *et al.*, 2002). Toxicosis has also been reported following inhalation or dermal absorption. Methanol is much more toxic to human beings and nonhuman primates than it is to other mammals. Methanol is metabolized by ADH to formaldehyde, which is oxidized to formic acid by formaldehyde dehydrogenase. In mammals other than primates, formic acid is metabolized relatively rapidly to carbon dioxide and water. Formic acid is metabolized less efficiently in primates.

### Mechanism of action

Formic acid is responsible for ocular and CNS lesions in primates as a result of inhibition of cytochrome oxidase (Roe, 1982). Blindness and permanent neurological abnormalities are common sequel in primates.

### Diagnosis and treatment

Clinical signs in animals other than primates are similar to those seen with ethanol toxicosis and are primarily

related to CNS depression and metabolic acidosis. Vomiting and abdominal pain may be seen. In primates, following the initial nausea and CNS depression, a latent period of approximately 12–24 h is followed by metabolic acidosis and impaired visual function. Laboratory findings in primates include hyperosmolality, increased anion gap, and severe metabolic acidosis (Bischoff, 2006a). Diagnosis can be made by history and measurement of blood methanol concentrations (or formic acid in primates).

Treatment in nonprimates is symptomatic and similar to treatment for ethanol toxicosis. Primates are treated with 4-methylpyrazole to compete with ADH and inhibit metabolism (Barceloux *et al.*, 2002) or, alternatively, with ethanol. Hemodialysis is also used to remove formic acid. Folic acid is given i.v. to enhance formic acid metabolism. It is probably inappropriate to treat methanol toxicosis in nonprimates with ethanol because ethanol contributes to the sedation, and the metabolites of methanol do not cause blindness in dogs, as they do in primates.

### Isopropanol toxicosis

Isopropanol (isopropyl alcohol) has the structural formula  $\text{CH}_3\text{CH}(\text{OH})\text{CH}_3$ ; a molecular weight of 60 Da; and is found in rubbing alcohol (70%), antifreeze, detergents, window cleaning products, and disinfectants. Ingestion is the usual cause of poisoning in humans, although toxicity from inhalation and topical absorption has been reported. Isopropanol toxicosis is rare in domestic animals, possibly due to its bitter taste. It has been reported in a horse that was mistakenly administered isopropanol via nasogastric intubation for colic; the isopropanol was mistaken for mineral oil (Somerville and Plumlee, 1996).

#### Toxicokinetics

Isopropanol is approximately twofold more toxic than ethanol. It is rapidly absorbed from the GI tract, and approximately 80% is metabolized to acetone, which is also a CNS depressant, but acetone has a much longer half-life (16–20 h) than does alcohol.

#### Diagnosis and treatment

Clinical signs associated with isopropanol toxicosis are similar to those for ethanol toxicosis and include CNS depression, hypotension, vomiting, and abdominal pain due to severe gastritis, which is secondary to direct irritation. The breath of patients who have ingested isopropanol has a characteristic acetone-like odor (Somerville and Plumlee, 1996). Treatment is supportive and includes fluids, correction of acid–base abnormalities, and assisted respiration if necessary (Oehme and Kore,

2006). Hemodialysis is effective in removing isopropanol and acetone, and 4-methylpyrazole will prevent the metabolism of isopropanol to acetone.

## GLYCOL TOXICOSES

### Propylene glycol toxicosis

Propylene glycol (1,2-propanediol) has the structural formula  $\text{C}_3\text{H}_8\text{O}_2$  and a molecular weight of 76 Da. It is one of the least toxic of the glycols, and it is used as automotive antifreeze, an industrial and pharmaceutical solvent, in cosmetics, and a processed food additive for human and animal consumption. Although it is considered non-toxic compared to EG, it causes CNS depression and lactic acidosis when ingested in large quantities. When used as an additive in semi-moist cat food, it historically caused Heinz body formation in erythrocytes but did not cause an anemia when ingested in small quantities (Christopher *et al.*, 1989a,b; Weiss *et al.*, 1990; Bauer *et al.*, 1992a,b). However, cats eating such diets were more susceptible to other additional causes of oxidative injury, and although overt anemia may not occur, red cells with Heinz bodies have a reduced life span. Consequently, it is no longer used as an additive in cat foods.

The oral median lethal dose for propylene glycol in dogs has been reported to be as low as 9 mL/kg (Bischoff, 2006b). Fatal cases of malicious propylene glycol toxicosis have been reported in dogs (Bischoff, 2006b). It is considered relatively unpalatable to dogs (Marshall and Doty, 1990). Fatal propylene glycol toxicosis was reported in a horse that was inadvertently given 7.6 mL/kg propylene glycol orally instead of mineral oil for potential grain overload (Dorman and Hascheck, 1991). The horse had a serum concentration of 900 mg/dL propylene glycol at the time of death, 28 h following ingestion. Cause of death was presumably respiratory arrest. Propylene glycol toxicosis has been reported in at least two other horses with colic in which propylene glycol was mistaken for mineral oil (Myers and Usenik, 1969; McClanahan *et al.*, 1998); both of these horses survived. In both cases, the horses were given approximately 6 mL/kg body weight via nasogastric tube. Heinz body formation also occurs in horses ingesting propylene glycol (McClanahan *et al.*, 1998). Propylene glycol may be used to treat and prevent bovine ketosis, which may partially explain the availability and apparent ease with which it is confused with mineral oil.

#### Toxicokinetics

Propylene glycol is rapidly absorbed in the GI tract and oxidized by ADH to D and L isomers of lactic acid,

resulting in lactic acidosis. Almost all propylene glycol is metabolized within 24 h of ingestion.

### Diagnosis and treatment

Clinical signs depend on the quantity ingested and may include depression, ataxia, muscle fasciculations, hypotension, osmotic diuresis, respiratory arrest, and circulatory collapse. Clinical signs in ruminants are similar to those seen in other species and include ataxia, depression, and recumbency (Pintchuck *et al.*, 1993). Laboratory findings include metabolic acidosis, increased anion gap, and hyperosmolality of the plasma and the presence of Heinz bodies in cats and horses. Diagnosis is usually based on history of exposure and can be confirmed by measuring propylene glycol concentrations in urine and serum by gas chromatography. Treatment for all species is supportive and includes correction of hydration and acid-base abnormalities.

### Butylene glycol toxicosis

Butylene glycol (1,2-, 1,3-, and 1,4-butanediol) has the structural formula  $C_4H_{10}O_2$  and a molecular weight of 90 Da. Butylene glycol is used as antifreeze, as an industrial cleaner, and in cosmetics. It is also a component of polyurethane and is used to make Spandex. Although no published reports of butylene glycol toxicosis in domestic animals were found in the literature, there are numerous reports of human intoxications from butylene glycol or the metabolite gamma-hydroxybutyrate (Dyer, 1991; Mack, 1993). Butylene glycol and the metabolite gamma-hydroxybutyrate are used as "recreational" drugs and were once marketed by health food stores as a food additive for body-builders and to treat depression and insomnia.

1,3-Butanediol has been used as an antidote for experimental EG toxicosis in dogs because it is a competitive substrate for ADH (Thrall *et al.*, 1982; Murphy *et al.*, 1984; Cox *et al.*, 1992). Although it was found to be a more effective antidote than ethanol, in that more unmetabolized EG was excreted in the urine in patients treated with 1,3-butanediol, CNS depression was as severe or more severe than that induced by ethanol therapy, and plasma hyperosmolality and metabolic acidosis were more severe than with ethanol therapy (Thrall *et al.*, 1982).

### Toxicokinetics

Butylene glycol is metabolized by ADH to acetoacetate and gamma-hydroxybutyrate, the so-called "date rape" drug.

### Mechanism of action

Butylene glycol is a CNS depressant much like ethanol, due to the effect of the gamma-hydroxybutyrate on the

CNS, and in large quantities can result in seizures and respiratory arrest.

### Treatment

Therapy for butylene glycol toxicosis in humans is supportive, similar to therapy for ethanol toxicosis.

### Ethylene glycol toxicosis

EG has the structural formula  $C_2H_6O_2$  and a molecular weight of 62 Da. EG is used primarily as an antifreeze and windshield de-icing agent. Its small molecular weight makes it very effective in lowering the freezing point of water. EG is also used as a cryoprotectant for embryo preservation; in the manufacture of polyester compounds; as a solvent in the paint and plastic industries; and as an ingredient in photographic developing solutions, hydraulic brake fluid and motor oil, and inks and wood stains (Davis *et al.*, 1997). The most readily available source of EG in the home is antifreeze solutions, which consist of approximately 95% EG.

### Toxicokinetics

Unlike the other alcohols (with the exception of methanol in primates) and glycols, the metabolites of EG are very toxic. EG is initially oxidized to glycoaldehyde by ADH, and glycoaldehyde is then oxidized to glycolic acid and then to glyoxylic acid. Glyoxylic acid is primarily converted to oxalic acid but may follow several metabolic pathways; end products may also include glycine, formic acid, hippuric acid, oxalomalic acid, and benzoic acid. Calcium is bound to oxalic acid, resulting in calcium oxalate crystal formation. Calcium oxalate crystal deposition is widespread but is most severe in the kidney, and crystalluria is a consistent finding in animals producing urine (Grauer *et al.*, 1984; Thrall *et al.*, 1984b).

### Mechanism of action

EG per se has no major effects other than GI irritation and increased serum osmolality. Glycoaldehyde, the first metabolite, is thought to be primarily responsible for CNS dysfunction; respiration, glucose, and serotonin metabolism are depressed; and CNS amine concentrations are altered (Parry and Wallach, 1974; Gordon and Hunter, 1982). Hypocalcemia secondary to calcium oxalate deposition may contribute to CNS signs, although the concurrent metabolic acidosis shifts calcium to the ionized active state, reducing the chances of hypocalcemia-associated clinical signs. Acidosis is also thought to lead to altered levels of consciousness and cerebral damage. Most of the metabolites are very cytotoxic to renal tubular epithelium, and some

renal epithelial and interstitial damage may be associated with calcium oxalate crystal formation within the renal tubules (de Water *et al.*, 1999). Renal epithelial cell death appears to be due primarily to destruction of cytoplasmic organelles, especially mitochondria (Bachman and Goldberg, 1971). Metabolic acidosis is often severe and has a deleterious effect on multiple organ systems. Glycolic acid accumulation is the primary cause of the metabolic acidosis associated with EG intoxication (Jacobsen *et al.*, 1984), although other acid metabolites also contribute. Glycolic acid accumulates because the lactic dehydrogenase enzyme that metabolizes glycolic to glyoxylic acid becomes saturated.

### Toxicity

Before it is metabolized, EG is no more toxic than ethanol, although EG is a more potent CNS depressant than ethanol (Berger and Ayyar, 1981). However, EG is biotransformed to highly toxic metabolites that result in severe metabolic acidosis and acute renal failure, hallmarks of EG poisoning (Thrall *et al.*, 1984b; Dial *et al.*, 1994a,b; Davis *et al.*, 1997). The minimum lethal dose of undiluted EG is 6.6 mL/kg in the dog (Kersting and Nielson, 1966) and 1.5 mL/kg in the cat (Milles, 1946).

### Clinical signs

Clinical signs are dose dependent and can be divided into those caused by unmetabolized EG and those caused by its toxic metabolites. The onset of clinical signs is almost always acute. Early clinical signs are usually observed 30 min after ingestion and often last until approximately 12 h after ingestion; they are primarily associated with EG-induced gastric irritation and high EG blood concentrations. These signs commonly include nausea and vomiting, CNS depression, ataxia and knuckling, muscle fasciculations, decreased withdrawal reflexes and righting ability, hypothermia, and osmotic diuresis with resultant polyuria and polydipsia (Grauer *et al.*, 1984; Thrall *et al.*, 1984b; Connally *et al.*, 1996). As CNS depression increases in severity, dogs drink less but osmotic diuresis persists, resulting in dehydration. In dogs, CNS signs abate after approximately 12 h, and patients may briefly appear to have recovered. Cats usually remain markedly depressed and do not exhibit polydipsia. Animals may be severely hypothermic, particularly if housed outside during the winter months. Clinical signs associated with the toxic metabolites are primarily related to oliguric renal failure, which is evident by 36–72 h following ingestion in dogs and by 12–24 h following ingestion in cats. Clinical signs may include severe lethargy or coma, seizures, anorexia, vomiting, oral ulcers and salivation, and oliguria with isosthenuria. Anuria often develops 72–96 h after ingestion. The kidneys are often swollen and painful, particularly in cats.

### Early laboratory abnormalities

Abnormal laboratory findings can also be divided into those associated with early EG intoxication, which may be related to the presence of EG *per se* or to its toxic metabolites, and those associated with late EG intoxication, most of which are related to renal failure. Early abnormalities are primarily due to the presence of acid metabolites of EG in the serum that result in metabolic acidosis and include decreased plasma bicarbonate concentration and increased anion gap. In addition, hyperphosphatemia may occur due to ingestion of a phosphate rust inhibitor present in some commercial antifreeze products (Grauer *et al.*, 1984; Connally *et al.*, 1996). The decreased plasma bicarbonate ( $\text{HCO}_3^-$ ) concentration can be seen as early as 1 h following EG ingestion. Metabolites of EG significantly increase the pool of unmeasured anions and cause an increased anion gap. The anion gap is increased by 3 h after ingestion, peaks at 6 h after EG concentration, which peaks 1–6 h following ingestion, and EG is usually no longer detectable in the serum or urine 48–72 h after ingestion (Thrall *et al.*, 1982; Grauer *et al.*, 1984; Dial *et al.*, 1994a,b). Kits (e.g., Ethylene Glycol Test Kit, PRN Pharmacol, Pensacola, FL) are available that accurately estimate blood EG concentrations with a minimum detection limit of 50 mg/dL, and the results correlate well with other established methods of measuring EG concentrations such as gas chromatography (Dasgupta *et al.*, 1995), although the presence of propylene glycol or glycerol in the blood may cause a false-positive test reaction. Ethanol and methanol do not result in a false-positive test result. Cats may be intoxicated with a lethal dose of EG that is below the 50 mg/dL detectable level of the EG test kit. Therefore, if the test kit is negative and historical findings as well as clinical signs are compatible with EG ingestion, the recommendation is to initiate appropriate therapy for EG intoxication as well as submit a serum sample to a reference laboratory capable of determining a quantitative concentration.

Determination of serum osmolality is also useful for diagnosing early EG toxicosis, although other osmotically active, low-molecular-weight alcohols and glycols also increase serum osmolality (Ammar and Heckerling, 1996). Serum osmolality is increased by 1 h after ingestion of EG, increasing in parallel with serum EG concentrations (Dial *et al.*, 1994a,b). When measured serum osmolality (by osmometry) is compared to calculated serum osmolality, the difference is referred to as the osmole or osmolal gap. If calculated osmolality is not provided on the biochemical profile printout, osmolality in mOsm/kg may be calculated using the following formula:

$$1.86 (\text{Na}^+ + \text{K}^+) + \text{glucose}/18 + \text{BUN}/2.8 + 9$$

Normal serum osmolality is 280–310 mOsm/kg, and the normal osmole gap is less than 10 mOsm/kg. Serum osmolality as high as 450 mOsm/kg and an osmole gap as high as 150 mOsm/kg may be seen 3 h after ingestion, depending on the quantity of antifreeze ingested (Jacobsen *et al.*, 1982b; Grauer *et al.*, 1984). Both the gap and the measured osmolality may remain significantly high for approximately 18 h after ingestion. Multiplication of the osmole gap by 5 yields an approximate serum EG concentration in mg/dL (Burkhart and Kulig, 1990). Each 100 mg/dL increment increase in EG concentration contributes approximately 16 mOsm/kg H<sub>2</sub>O to the serum osmolality (Eder *et al.*, 1998). Simultaneous or sequential increases in osmole and anion gaps are very suggestive of EG intoxication. As EG is metabolized, its contribution to the osmole gap diminishes because the accumulating negatively charged metabolites do not contribute to the osmole gap (Eder *et al.*, 1998). Two types of instruments are used to measure osmolality – freezing point osmometers and vapor pressure osmometers. Because EG is nonvolatile (boiling point, 197°C), it is detected by either the freezing point or vapor pressure methods. However, methanol, ethanol, and other volatile compounds, although contributing to serum osmolality, may go undetected if assayed by the vapor pressure method. Most clinical laboratories use the freezing point method (Kruse and Cadnapaphornchai, 1994). Osmolality can be measured using serum or plasma; if the latter is used, heparin is the preferred anticoagulant. Other anticoagulants, such as EDTA, can markedly increase osmolality and can result in spurious increases in the osmole gap (Kruse and Cadnapaphornchai, 1994).

Dogs are isosthenuric (urine specific gravity of 1.008–1.012) by 3 h following ingestion of EG due to osmotic diuresis and serum hyperosmolality-induced polydipsia (Grauer *et al.*, 1984; Dial *et al.*, 1994a). The urine specific gravity in cats is also decreased by 3 h after ingestion but may be above the isosthenuric range (Dial *et al.*, 1994b; Fogazzi, 1996). Calcium oxalate crystalluria is a common finding and may be observed as early as 3 and 6 h after ingestion in the cat and dog, respectively, as a result of oxalic acid combining with calcium (Dial *et al.*, 1994a,b). Calcium oxalate monohydrate crystals are variably sized, clear, six-sided prisms (Figure 60.1) (Scully *et al.*, 1979; Godolphin *et al.*, 1980; Terlinsky *et al.*, 1981; Jacobsen *et al.*, 1982a; Kramer *et al.*, 1984; Foit *et al.*, 1985; Thrall *et al.*, 1985; Steinhart, 1990). In animals and people poisoned with EG, the monohydrate form is observed more frequently than the dihydrate form, which appears as an envelope or Maltese cross (Connally *et al.*, 1996; Eder *et al.*, 1998). Dumbbell or sheaf-shaped crystals are observed infrequently. The detection of calcium oxalate crystalluria, particularly the monohydrate form, provides strong supporting evidence for the diagnosis of EG poisoning (Fogazzi, 1996). Urinary pH consistently decreases following EG ingestion.

**FIGURE 60.1** Calcium oxalate monohydrate crystals (polarized light) from a dog with EG toxicosis.

Another diagnostic procedure that may be helpful in detecting early EG intoxication is examination of the oral cavity, face, paws, vomitus, and urine with a Wood's lamp to determine whether they appear fluorescent. Many antifreeze solutions manufactured today contain sodium fluorescein, a fluorescent dye that aids in the detection of leaks in vehicle coolant systems. The dye is excreted in the urine for up to 6 h following ingestion of the antifreeze (Winter *et al.*, 1990). A negative test does not eliminate the possibility of EG ingestion because not all antifreeze solutions contain the dye.

#### *Late laboratory abnormalities*

With the onset of renal damage and subsequent decreased glomerular filtration, serum creatinine and blood urea nitrogen (BUN) concentrations increase. In the dog, these increases begin to occur between 24 and 48 h following EG ingestion. In the cat, BUN and creatinine begin to increase approximately 12 h after ingestion; however, because cats do not develop polydipsia, this may be in part due to dehydration. Serum phosphorus concentrations increase at this time due to decreased glomerular filtration. Hyperkalemia develops with the onset of oliguria and anuria. Serum calcium concentration is decreased in approximately half of patients (Thrall *et al.*, 1984b; Connally *et al.*, 1996) and is due to formation of insoluble calcium oxalate. Clinical signs of hypocalcemia are infrequently observed because acidosis results in a shift to the ionized, physiologically active form of calcium. Serum glucose concentration is increased in approximately 50% of dogs and cats (Thrall *et al.*, 1984b; Connally *et al.*, 1996) and is attributed to inhibition of glucose metabolism by aldehydes, increased epinephrine and endogenous corticosteroids, and uremia. Animals presenting with late EG poisoning are likely to have little or no osmole gap increase but will have an increased osmolality (whether calculated or

measured) because of the azotemia and hyperglycemia. Animals remain isosthenuric in the later stages of toxicosis due to renal dysfunction and impaired ability to concentrate urine. Calcium oxalate crystalluria persists for as long as animals are producing urine. Urine abnormalities associated with renal damage may include hematuria, proteinuria, and glucosuria. Granular and cellular casts, white blood cells, red blood cells, and renal epithelial cells may be observed in the sediment of some patients (Thrall *et al.*, 1984b; Connally *et al.*, 1996).

### Treatment

Therapy for EG poisoning is aimed at preventing absorption, increasing excretion, and preventing metabolism of EG. Supportive care to correct fluid, acid-base, and electrolyte imbalances is also helpful. Although therapeutic recommendations have traditionally included induction of vomiting, gastric lavage, and administration of activated charcoal (Thrall *et al.*, 1995, 1998), it is likely that these procedures are not beneficial because of the rapidity with which EG is absorbed (Davis *et al.*, 1997). The most critical aspect of therapy is based on prevention of EG oxidation by ADH, the enzyme responsible for the initial reaction in the EG metabolic pathway (Parry and Wallach, 1974). Typically, dogs must be treated within 8 h following ingestion and cats must be treated within 3 h for treatment to be successful (Dial *et al.*, 1994a,b). However, this is somewhat dependent on the amount of EG ingested. Historically, treating EG toxicosis has been directed toward inhibiting EG metabolism with ethanol, a competitive substrate that has a higher affinity for ADH than EG (Penumarthy and Oehme, 1975; Bostrom and Li, 1980). Ethanol has numerous disadvantages because it enhances many of the metabolic effects of EG. Both ethanol and EG are CNS depressants, and it is the compounded CNS depression that most limits the usefulness of ethanol as an antidote. Additional disadvantages of ethanol treatment include its metabolism to acetaldehyde, which impairs glucose metabolism and is a cerebral irritant. Ethanol also contributes to metabolic acidosis by enhancing the formation of lactic acid from pyruvate and may potentiate hypocalcemia (Money *et al.*, 1989). Moreover, ethanol compounds the effects of EG-induced osmotic diuresis and serum hyperosmolality (Kruse and Cadnapaphornchai, 1994).

4-Methylpyrazole (fomepizole) has become the preferred antidote in dogs (Grauer *et al.*, 1987; Dial *et al.*, 1989; Connally *et al.*, 1996) and cats (Thrall *et al.*, 2006; Connally *et al.*, 2010). Fomepizole is an ADH inhibitor, not a competitive substrate, and it does not induce CNS depression (in dogs), diuresis, or hyperosmolality at the recommended dosage. The recommended dose of fomepizole for dogs is 20 mg/kg body weight i.v. initially, followed by 15 mg/kg i.v. at 12 and 24 h and 5 mg/kg i.v. at 36 h (Grauer *et al.*,

1987; Connally *et al.*, 1996; Thrall *et al.*, 2006). Cats must be given a much higher dose of fomepizole than dogs because feline ADH is less effectively inhibited by fomepizole than is canine ADH (Connally *et al.*, 2000, 2010). Cats are initially treated with 125 mg/kg fomepizole i.v. followed by 31.25 mg/kg i.v. fomepizole at 12, 24, and 36 h. The only adverse clinical sign that the authors have observed is CNS depression that appears to be fomepizole related (Connally *et al.*, 2010). If ingestion of a large dose of EG is suspected, repeating serum quantification tests can be performed to determine whether continuation of therapy beyond 36 h is necessary. Alternatively, additional doses of fomepizole can be administered empirically. Fomepizole is commercially available as Antizol-Vet (Orphan Medical, Minnetonka, MN), which can be conveniently reconstituted. Appropriate therapy also consists of i.v. fluids to correct dehydration, increase tissue perfusion, and promote diuresis. The fluid volume administered should be based on the maintenance, deficit, and continuing loss needs of the patient. Frequent measurement of urine production, serum urea nitrogen and creatinine, and blood pH, bicarbonate, ionized calcium, and electrolytes daily or twice daily will help guide fluid and electrolyte therapy (Grauer, 1998). Bicarbonate should be given slowly i.v. to correct the metabolic acidosis. Hypothermia can be controlled with blankets or the use of a pad with circulating warm water.

In animals that are azotemic and in oliguric renal failure on presentation, almost all of the EG has been metabolized, and treatment to inhibit ADH is likely to be of little benefit. However, ADH inhibitors should be given up to 36 h following ingestion to prevent the metabolism of any residual EG. Fluid, electrolyte, and acid-base disorders should be corrected and diuresis established, if possible. Diuretics, particularly mannitol, may be helpful. The tubular damage caused by EG may be reversible, but tubular repair can take weeks to months. Animals may take up to 1 year following EG toxicosis to regain concentrating ability, and some remain isosthenuric. Supportive care to maintain the patient during the period of renal tubular regeneration is necessary, and peritoneal dialysis may be useful (Shahar and Holmberg, 1985; Fox *et al.*, 1987; Crisp *et al.*, 1989). Hemodialysis has been attempted in dogs with EG-induced renal failure (DiBartola *et al.*, 1985) and has been shown to have a relatively good success rate in cats with acute renal failure (Langston *et al.*, 1997). Renal transplantation has also been used with variable success in cats with renal failure (Gregory *et al.*, 1992; Mathews and Gregory, 1997) and has been described in dogs (Nemeth *et al.*, 1997).

### Prognosis

EG has a very high potential for a lethal outcome, but with early recognition of the syndrome and timely institution of therapy, animals can be saved. The quantity of

EG ingested, rate of absorption, and time interval prior to institution of therapy are variables that affect the prognosis. The prognosis is excellent in dogs treated with fomepizole within 5h of ingesting EG. In a retrospective study of dogs with confirmed EG poisoning, all of the dogs that were azotemic when initially treated died. Of the dogs that did not have azotemia when initially treated, approximately 90% survived (Connally *et al.*, 1996). The prognosis for cats is reasonably good if treatment is instituted within 3h following ingestion (Dial *et al.*, 1994b). In contrast, the prognosis in humans who survive the initial syndrome of severe acidosis is very good. Terminal renal failure in humans is rare, and most human patients regain renal function by 2 months following EG poisoning (Davis *et al.*, 1997) likely due to the effectiveness of hemodialysis therapy in humans (Christiansson *et al.*, 1995).

## CONCLUSIONS

Ethanol, methanol, isopropanol, propylene glycol, butylene glycol, and marijuana toxicosis can produce ataxia and other CNS signs similar to those seen in acute EG poisoning but are much less common than EG toxicosis (Godbold *et al.*, 1979; Hurd-Kuenzi, 1983; Thrall *et al.*, 1984a; Suter, 1992). These disorders can be differentiated by the diagnostic laboratory tests discussed previously. Other causes of an increased anion gap include diabetic ketoacidosis and lactic acidosis; these disorders can also be differentiated by appropriate laboratory tests. Other causes of increased osmolality include ethanol, isopropanol, methanol, and propylene glycol toxicosis. Ethanol, like EG, can also produce hypocalcemia (Money *et al.*, 1989). Other differentials for acute renal failure include leptospirosis, ibuprofen and other nonsteroidal anti-inflammatory drug toxicosis, aminoglycoside antibiotics, hemolyticuremic syndrome, cholecalciferol toxicosis, grape and raisin toxicosis in dogs, and ingestion of oxalate-containing plants such as philodendron and lily toxicosis in cats (Brown *et al.*, 1985, 1996; Spyridakis *et al.*, 1986; Gunther *et al.*, 1988; Peterson *et al.*, 1991; Holloway *et al.*, 1993; Rivers *et al.*, 1996; Vaden *et al.*, 1997a,b; Poortinga and Hungerford, 1998; Forrester and Troy, 1999; Adin and Cowgill, 2000; Hovda, 2000; Rumbelha *et al.*, 2000; Singleton, 2001; Langston, 2002; Tefft, 2004). The majority of dogs with grape and raisin toxicosis are hypercalcemic, as are animals with cholecalciferol toxicosis (Fooshee and Forrester, 1990; Gwaltney-Brant *et al.*, 2001); hypercalcemia is not associated with EG toxicosis (Thrall *et al.*, 1984b; Connally *et al.*, 1996). Acute renal failure must be differentiated from acutely decompensated chronic renal failure. Carbamylated hemoglobin concentration

has been shown to be useful in making this differentiation (Vaden *et al.*, 1997b; Heiene *et al.*, 2001). In addition, animals with chronic renal failure may be anemic and in poor body condition. A history of the duration of clinical signs is also helpful. Continuing to increase the awareness of the toxicity of EG, as well as other alcohols and glycols, will aid in preventing exposure and result in earlier presentation of animals.

# Petroleum

*Robert W. Coppock and Ralph G. Christian*

## INTRODUCTION

This chapter primarily discusses the toxicology of crude petroleum and pollution generated during the production of petroleum. Emphasis is placed on domestic animals. Domestic and wild animals can also be exposed to environmental petroleum. Crude petroleum can be released into the environment during well blowouts, leaks at wellheads, pipeline leaks, land and sea shipping disasters, and other events and activities. Emissions can be from venting storage tanks, blowouts of gas wells, burning petroleum that has been spilled, or burning unwanted gaseous material. Production of crude petroleum presents two major toxicological issues: exposure of animals to the primary raw product and exposure to pollution generated by the production of crude petroleum. Crude petroleum is designated as sweet or sour based on sulfur content, primarily hydrogen sulfide ( $H_2S$ ). Sour petroleum, especially sour gas, is an economic source of sulfur sold as a commodity. Some governments exempt waste generated in oil fields from hazardous waste regulations. In many geographic regions, such as western Canada, the provincial governments own the majority of mineral resources and can require landowners to provide land leases for oil and gas exploitation. Uneconomical products such as gas including  $H_2S$  coming from crude oil and bitumen can be piped to a flare pipe and burned or vented into the atmosphere. Domestic and wild animals are exposed to pollution from oil and gas activity. Issues exist in using agricultural lands for waste disposal and food production. Oil pits also present a risk for wildlife (Trail, 2006).

Oil pits contain waste fluids that may be stored in pits, open tanks, and other sites accessible to wildlife and domestic animals.

Intoxication of animals with crude and refined petroleum does occur. The two major conditions for exposure are spills and leaks of petroleum into aquatic and terrestrial systems. There is an agricultural and petroleum industrial interface from multiple use of lands for agricultural and petroleum production. Land located in remote regions of the world is also used for oil and gas production. Land uses by the petroleum industry include oil and gas well sites, tank battery sites, gathering sites, sweet and sour gas plants, compressor stations, and pipelines. Crude petroleum and chemicals used in the oil fields can be spilled. The dermal, inhalation, and oral routes of exposure can subsequently poison domestic and wild animals. Birds and mammals can have oil soiling their feathers and fur, respectively. Oral ingestion also occurs from dermal exposure and during preening. Loss of insulation protection of feathers and fur can lead to hypothermia. Oil and gas field operations have intentional and unintentional air emissions. The production of sour gas and the removal of sulfur (sour gas processing plants) present toxicology issues. Animals are poisoned when petroleum products are used as medicaments, containers containing petroleum products are used for animal feedstuffs and applications of parasiticides, petroleum containers are left open and unattended, and domestic spills occur during transportation and use. Water can accompany gas and oil to the surface. This is commonly referred to as production water, and it can be high in brine and salt poisoning can occur. Abandoned oil and gas wells can seep petroleum and brine water to the surface.

OIL AND GAS WELL DRILLING  
AND COMPLETING

Drilling

Oil and gas wells are drilled into oil- and gas-producing formations that exist at varying depths below the surface. During drilling operations, drilling fluids are used to cool and lubricate the drill bit, support the walls of the borehole, and move the cuttings to the surface. The weight of the drilling fluid (mud) controls subsurface pressure and aids in preventing blowouts. Different types of drilling fluids and additives are used for drilling the different geologic zones and penetrating the formation. There are different preferences for the composition of drilling fluids, cost considerations, and requirements of the drilling techniques employed. Wide variations in the chemical composition of drilling fluids are found when companies are drilling within the same oil field

(Edwards and Gregory, 1991). Drilling and petroleum companies can be reluctant to disclose substances added to drilling fluids.

Two basic types of drilling fluids used are the water-based drilling fluid and the non-aqueous drilling fluids. Water-based drilling fluids generally consist of salts, bentonite clay, and barium sulfate for density, and other chemicals are added to give desired properties such as lubrication and reduction of foaming (Table 61.1). Brine or freshwater can be used in water-based drilling fluids. Lignite or lignosulfonate, caustic chrome salts, and other compounds (for example, starches and cellulosic polymer) may also be used. In the non-aqueous drilling fluids (invert drilling fluids), freshwater or brine water is emulsified in a hydrocarbon phase. Emulsifiers are used to disperse the water in the hydrocarbons. The water emulsion is generally less than 1 μm in diameter. Diesel fuel is often used as the hydrocarbon in land-based drilling operations. Hydrotreated mineral oil can be used, which has a low content of polyaromatic

TABLE 61.1 Examples of drilling mud additives, substances used to stimulate oil and gas wells, and substances used in the production of oil and gas

Function of substance	Example substance <sup>a</sup>	Function of substance	Example substance <sup>a</sup>
Acids used for well stimulation and other uses	Acetic acid	Breakers, emulsion/gels	Ammonium persulfate
	Acetic anhydride		Benzoic acid
	Benzoic acid		Sodium acetate
	Formic acid		Sodium persulfate
	Hydrochloric acid		
	Hydrofluoric acid	Cement additives	Aluminum (coated)
Add weight to drilling fluid	Sulfuric acid		Calcium chloride
	Attapulgate		Cellulose flakes
	Barium sulfate (Barite)		Cellulose polymer
	Bentonite		Gilsonite
	Galena (lead sulfate)		Gypsum
	Hematite (iron oxide)		Latex
	Siderite (iron carbonate)		Lignosulfonates
Antihydrate (block formation of hydrates)	Jel Chem (e.g., potassium silicate)		Lime
	Alcohols		Long-chain alcohols
	Methanol		Potassium chloride
Biocides	Glycols		Sodium chloride
	Acrolein		Sodium metasilicates
	Anhydrous ammonia	Corrosion inhibitors	Acetylenic alcohols
	Amines		Amine formulations
	Chlorinated phenols		Ammonium bisulfite
	Formaldehyde		2-Butoxyethanol
	Glutaraldehyde		Ironite sponge
	Isopropanol		4,4'-Methylenedianiline
	Methylene bithiocyanate		Paraformaldehyde
	2-(Thiocyanatomethylthio)-1,3-benzothiazole		Sodium chromate
	Thiazolin		Sodium dichromate
	Quaternary ammonium		Sodium metasilicate
			Sodium polyacrylate
			Thiazolin

(Continued)

TABLE 61.1 (Continued)

Function of substance	Example substance <sup>a</sup>	Function of substance	Example substance <sup>a</sup>
Deflocculants	Zinc carbonate	Propping agents	Bauxite
	Zinc oxide		Resin-coated sand
	Zinc lignosulfonate		Sand
			Zirconium compounds
	Acrylic polymer	Salt solutions	Aluminum chloride
	Calcium lignosulfonate		Ammonium chloride
	Chrome-free lignosulfonate		Calcium bromide
	Chromium lignosulfonate		Calcium chloride
	Iron lignosulfonate		Calcium sulfate
	Quebracho		Ferrous sulfate
	Sodium acid pyrophosphate (SAPP)		Potassium chloride
	Sodium hexametaphosphate		Sodium chloride
	Sodium phosphate (oilfos)		Sodium sulfate
	Sodium tetrphosphate		Zinc bromide
	Sodium tripolyphosphate (STP)		Zinc chloride
	Styrene, maleic anhydride copolymer salt		Zinc sulfate
	Sulfomethylated tannin		
Defoaming agents	Aluminum stearate	Scale inhibitors	Ethylenediaminetetraacetic acid (EDTA)
	Fatty acid salt formation		Inorganic phosphates
	Mixed alcohols		Nitrilotriacetic acid (NTA)
	Silicones		Organic phosphates
	Tributylphosphate		Phosphonates
Dispersant – thinner	Causticized metal lignite	Solvents	Polyacrylate
	Ferrochrome lignosulfonate		Polyphosphates
	Sodium tetrphosphate		Acetone
	Lignite		Aliphatic hydrocarbons
	Lignosulfonates		<i>t</i> -Butyl alcohol
Fluoride generators	Ammonium bifluoride		Carbon tetrachloride
	Ammonium fluoride		Chloroform
Lubricants/friction reducers	Acrylamide methacrylate copolymers		Diacetone alcohol
	Graphite		Diesel oil
	Lead grease		Ethylene glycol monobutyl ether
	Lithium grease		Kerosene
	Mineral oil formulations		Isopropanol
	Molybdenum grease		Methyl ethyl ketone (MEK)
	Motor oil		Methyl isobutyl ketone (MIBK)
	Organo-fatty acid salt		Methylene chloride
	Petroleum grease		Methanol
	Reprocessed motor oil		Naphtha
	Sulfonates		1,1,1-Trichloroethane
	Vegetable oil formulations		Toluene
			Turpentine
Multiple uses	Ammonium nitrate		Xylene
Oil-based drilling fluids	Potassium nitrate	Surfactants – emulsifiers	General categories
	Amid polymer formulations		Cationic
	Amine-treated lignite		Non-ionic
	Asphalt		Anionic
	Diesel		Amides
	Gilsonite		Arylalkyl sulfonic acid
	Mineral oil		Fatty alcohols
	Organophilic clay		Glycols
	Organophilic hectorite		Isopropanol
	Petroleum distillate		Modified tall oils (from tree resin byproduct of wood pulp industry)
	Polyethylene powder		Nonylphenol ethoxylates
Oxygen remover pH control	Polymerized organic acids		Oxyalkylated phenolic compounds
	Ammonium bisulfite		Petroleum naphtha
	Calcium hydroxide		Polyamines (diethylenetriamine and triethylenetetramine)
	Potassium hydroxide		
	Soda ash (sodium carbonate)		
	Sodium bicarbonate		
	Sodium hydroxide		

<sup>a</sup>Some items on this list may have historic use and may be in abandoned sumps.

hydrocarbons. Synthetic hydrocarbons and polymers can also be used. Drilling mud can also contain heavy metals, especially aluminum, cadmium, chromium including chromates, copper, iron, lead, mercury, and zinc. Drilling wastes are representative of the formations encountered during the drilling operations. If radioactive materials are encountered in the formations, radioactive materials and gas can be in drilling fluids and drill cuttings.

### Completion and formation fracturing (fracking)

Regulations exist in most governmental jurisdictions to protect groundwater reservoirs. During the drilling of the oil or gas wells, a surface casing is inserted and cemented in place to protect groundwater. Regulations specify the depth that the casing has to extend beyond freshwater aquifers. During the cementing operation, cement is pushed down around the casing, and the hardened cement is the seal between the borehole and the casing. A blowout preventer is attached to the casing. The production tubing is inserted into the borehole and extends from the surface to the oil- or gas-bearing formation. Production of oil and gas is from the tubing. Incomplete or faulty cement jobs and casing failure can result in contamination of the groundwater with crude oil and natural gas.

Oil- and gas-bearing formations are porous, with the oil and gas contained within the pores. To stimulate production, the formation is fractured. In the past, fracturing was done with explosives. Hydraulic fracturing is done by pumping chemicals and solids down the hole and fracturing the formation. A large volume of water (~2 million L) and a variety of substances can be used during fracking operations (Finkel and Law, 2011). Acids can be pumped down the formation to form fractures by dissolving the formation. Propping agents such as resin-treated sand are placed in the fractures to prevent closure.

Oil and gas production can use large quantities of surface and groundwater. The use of water generally increases with depletion of oil in the underground reservoir. Large quantities of water and steam can also be used for *in situ* extraction of bitumen. In both of these operations, water or steam is injected into the formation, sometimes at very high pressure. The water remains in the formation, and oil or liquid bitumen is extracted. The loss of water to underground formations is an issue in the more arid regions of the world, including the western United States and Canada. Arsenic naturally occurring in groundwater can increase as the level of water in the aquifer is decreased when groundwater is pumped out for steam production.

## COAL BED METHANE AND SHALE GAS

The production of coal bed methane can create water issues. Coal bed methane is produced by the *in situ* removal of methane from coal deposits. It is estimated that trillions of cubic meters of coal bed methane reserves exist, making this an attractive source of natural gas. The procedure to produce coal bed methane is to drill a well into the coal deposit and inject liquids under high pressure to hydraulically fracture (fracking) the coal seam (Cobb, 2003; Keith *et al.*, 2003; Young, 2005). After fracking, water is pumped from the coal bed, and the decrease in pressure allows methane to escape into the natural and man-made cleats (cracks in the coal bed). Generally, a larger number of wells are drilled for coal bed methane production than for conventional natural gas production. Coal beds can occur in aquifers. In coal bed methane production, huge quantities of water can be removed from underground aquifers, and aquifer drawdown can affect an area as large as a township. In some regions, the produced water is high in salts (total dissolved solids), and surface water and soil pollution from this water is a significant problem. The saltwater produced in coal bed methane production can be high enough to cause sodium ion intoxication in livestock.

Shale formations are a source of oil and natural gas being exploited by new drilling and fracking technologies. Emerging issues are damage to domestic water supplies and deposits containing radioisotopes.

## SOURCES OF TOXIC SUBSTANCES

Chemicals associated with petroleum intoxication in cattle are the gaseous, liquid, and solid crude petroleum and chemicals associated with the production of natural gas, crude oil, and bitumen, respectively. As it comes from the wellhead, crude natural gas may have volatile liquids and may contain H<sub>2</sub>S and other forms of sulfur, including the polyaromatic thiophenes (Kropp and Fedorak, 1998). Natural gas that contains H<sub>2</sub>S is called sour gas. In addition, a large variety of chemicals are used in the production of crude petroleum. Sour gas can have the H<sub>2</sub>S removed and the sulfur gas disposed of by burning in flare stacks.

### Emissions

Flaring is a method used in the petroleum industry to dispose of unwanted flammable gases. In contrast to an incinerator, a flare produces more products of

incomplete combustion. A flare is essentially burning of gaseous material at the end of a vertical or horizontal pipe. The horizontal flare pipe may end in a pit called a flare pit. Wind and liquids in the flare gas remarkably reduce the efficiency of a flare for burning gaseous waste (Stroscher, 1996). Flaring is done for emergency release of flammable gases, process flaring to dispose of unwanted gases, and production testing. Solution gas is a product derived from crude petroleum when the pressure is reduced to atmospheric pressure. This gas can be flared as an unwanted product. Gas wells are production tested after completion by connection to a flare stack or an incinerator. Production testing is done to remove chemicals from the formation that would corrode pipelines and other equipment and to estimate the economic productivity of a gas well. The gas well is connected to a flare, and the emissions from the well are burned. Stroscher (1996) provided insight into the chemical complexity of flare emissions. Toxic emissions can include a wide variety of combustion products such as chlorinated dibenzodioxins and furans if chlorine and favorable combustion conditions are present (Buckland *et al.*, 2000). Burning sulfur-containing oil field wastes can produce sulfur dioxide (SO<sub>2</sub>), reduced sulfur compounds (including carbon disulfide, carbonyl sulfide, and thiophenes), and polyaromatic hydrocarbons.

## Production water

Production water is water that is brought to the surface during the production of oil and natural gas. Production water can be high in total dissolved solids (TDSs), and ingestion of production water can induce salt (sodium ion) poisoning. Production water can have a unique ratio of ions, and this ratio generally can be distinctly different from TDSs in groundwater. Livestock producers in the more arid regions may use production water that is low in TDSs, and produced water may be lower in TDSs than water from shallow aquifers. Production water can be high in sulfates. Cattle consuming water high in sulfate have increased risk for thiamine-responsive polioencephalomalacia, and the risk increases with decreased dietary copper (Gould, 1998).

## Well rework and pipeline maintenance

A variety of chemicals are used during rework (maintenance of downhole equipment) operations. Spillage of these chemicals occurs, and livestock poisonings have been reported (Monlux *et al.*, 1971). Detergents, surfactants, and other substances can be used during rework operations (Table 61.1). Detergents generally increase

the gastrointestinal absorption of hydrocarbons. Acids, solvents, anticorrosives, and chelating compounds can also be used. Some of these compounds are intrinsically toxic and can enhance the toxicity of other substances. Chelating and descaling agents may increase the bioavailability of chemicals that otherwise would be considered to have a low order of toxicity. Downhole equipment can be laid out at unsecured sites and cattle will lick the petroleum and other substances from the equipment.

Pigging is placing a scraper ("pig") in a pipeline to remove biofilms, wax, and other substances. The pig may contain electronic equipment to inspect the pipeline for corrosion and other defects. A variety of organic and inorganic chemicals, including biocides, solvents, surfactants, and anticorrosive chemicals, can be used in pigging operations. These chemicals are caught in a tank located at an instillation called a "pig trap." Large amounts of these substances can be spilled at a pig trap, and contamination of groundwater used for livestock can occur.

## Sumps and contaminated soil

A sump is generally a pit used for disposal of oil field drilling waste. Many government jurisdictions have outlawed buried sumps. Sump tanks are used and waste is disposed at a proper waste disposal site. The chemical composition of drilling sumps is highly variable and reflects chemicals used in drilling oil and gas wells, heavy metals in formations penetrated by the drilling operation, fracking substances, and other materials disposed of in the sumps (Heitman, 1986; Wascom, 1986). Sump pits vary considerably in size from a small lot to larger than a football field, and they may not be adjacent to oil and gas well sites. Buried sumps can be limited to a series of backhoe trenches. Remote sumps miles from any oil or gas wells have been used for waste disposal. Sump pits can be a ticking time bomb, and environmental issues arise because the current landowner may not be aware that a site exists. Although some governments have progressed in regulating sump pits, old sumps can be a cause of concern (Murphy *et al.*, 1986). A sump can literally be a miniature abandoned hazardous waste site that has defaulted to the legal landowner. Issues arise regarding cleanup of these old sites, and many jurisdictions have laws that declare the legal landowner responsible. Some banks in Canada have given farmland zero value for loans because of old oil and gas well sump pits. In some areas of the world, rough lands with buried oil field sumps have become desirable building sites. Houses and barns have been built on or adjacent to old sumps, and individuals have planted gardens over old sumps. Surface water from rainfall events and melting snow can extrude drilling waste from sumps to the

surface, and these substances can be a toxicology hazard (Mostrom *et al.*, 1993). Domestic and wild animals can be attracted to these areas.

Drill cuttings and spent drilling fluids eventually become wastes and can be disposed of in sump pits. For example, a well 20 cm in diameter and 1000 m deep generates approximately 30 m<sup>3</sup> of drill cuttings. The volume of drilling fluids accumulating in the drilling sump varies from 789 to greater than 160,000 m<sup>3</sup>. The general rule is 0.5 m<sup>3</sup> of drilling waste per meter of depth. Some of the drilling wastes are spread on agricultural lands because of perceived value for the content of nitrogen, potassium, and other plant nutrients. The analytical chemistry of oil field waste can be incomplete and may not reflect the true hazard from spreading these substances on agricultural lands. Issues from this practice include puddling of the drilling fluids and cattle drinking from the puddles. Waste drilling fluids and drill cuttings are disposed of in sumps on the oil lease or at lease sites called remote sumps.

Rain and snow runoff water can extrude contaminants from sumps and contaminated soil. Extrusions from a drilling sump containing invert-drilling fluid have been associated with maladies in cattle (Mostrom *et al.*, 1993). Extrusions from an invert sump contaminated a pasture. Cows grazing this pasture had calves that were stunted. Necropsy findings were abnormal epiphyseal plates in the long bones and myeloid-like bodies in the proximal tubular cells of the kidney (Mostrom *et al.*, 1993). The activities of cytochrome P450 mixed function oxidase enzymes were also elevated. Sheep have been poisoned following extensive rains that caused extrusion of natural gas condensate from contaminated soil (Adler *et al.*, 1992). Valve failure on a condensate storage tank resulted in the soil being contaminated, and subsequent rains extruded condensate from the soil outside the perimeter fence of the lease. Eight ewes were found dead the first day, and the extrusion area was fenced but ewes continued to succumb during a 21-day period. Clinical signs observed were depression, fever, gasoline-like odor to the breath, dyspnea, anorexia, ruminal atony, bloody diarrhea, weight loss, nasal discharge, and recumbency. A gasoline-like odor was detected in ewes necropsied 10 days, but not 18 days, after the last exposure. Cattle grazing in the vicinity of a petroleum complex in India enhanced the presence of As, Ba, Br, Cr, Hg, and Fe in rumen fluid ash, and the elements Na, K, Cl, Cu, Mn, and P were depleted (Garg *et al.*, 1996). The elements were determined by neutron activation.

## Ions

Drilling sumps can also contain high levels of sodium (Na<sup>+</sup>) and potassium (K<sup>+</sup>) ions (Darley and Gray, 1988).

Heavy rainfall can extrude potassium salts from old sumps. The extrusions can be confused with whitish discoloration that occurs in naturally occurring alkali areas. When given by oral or intravenous routes, K<sup>+</sup> has an essentially equal order of toxicity (Ward, 1966a). The oral lethal dose of K<sup>+</sup> in a 475-kg cow has been reported to be 238 mg of K<sup>+</sup> (as KCl)/kg body weight (BW) (Ward, 1966b). Because of decreased renal excretion of K<sup>+</sup>, calves are more sensitive to K<sup>+</sup> poisoning than cows, with a lethal dose of 1.73 g of K<sup>+</sup>/kg BW (Blaxter *et al.*, 1960; Ward, 1966a; Neathery *et al.*, 1979). In high doses, K<sup>+</sup> targets contraction mechanisms in cardiac and skeletal muscles. In calves given K<sup>+</sup> by intravenous infusion, changes in the electrocardiograph were observed. With increasing plasma concentrations of K<sup>+</sup>, the QRS interval increases, the P–R interval decreases, P waves decrease, and the Q–T interval becomes very prolonged. With increasing concentrations of K<sup>+</sup> in plasma, the QRS complex becomes disorganized, and atrial flutter, atrioventricular block, and occasional to complete ventricular arrest occur. With increasing concentrations of K<sup>+</sup> in plasma, respiration also increases in rate and amplitude (Bergman and Sellers, 1953, 1954). Altering the K<sup>+</sup>:Na<sup>+</sup> ratio in the rumen has been associated with bloat (Turner, 1981).

Sodium ion poisoning can also occur. Clinical signs are muscle twitching, ataxia, bruxism, aggression, circling, and head pressing. Ingestion of brine water causes dehydration (sunken eyes and loss of plasticity of the skin). Sodium ion in the blood increases, and the electrophysiology of excitable tissues is disrupted. The pathology of Na<sup>+</sup> poisoning in cattle can be variable (Scott, 1924; McCoy and Edwards, 1980; Sullivan, 1985). Ingestion of concentrated Na<sup>+</sup> produces marked congestion of the omasal and abomasal mucosa. Gut contents are fluid, and hemorrhage may cause dark discoloration. Edema of the skeletal muscles and hydropericardium can occur. Edema of the brain can also occur, and an eosinophilic infiltration of the Virchow–Robin spaces may or may not be observed in cattle. Lesions of polioencephalomalacia can also be present. Birds can be poisoned by sodium chloride (Bollinger *et al.*, 2005).

## Lubricant additives

Oil field companies have a substantial investment in surface equipment. This can range from simple reciprocating pumps to complex high-volume pipeline pumping equipment. This equipment can have special lubrication requirements. Manufacturers of specialty lubricants often guard knowledge of the additives in their products as intellectual property. Thus, it can be difficult to obtain this information. It is well known that the *ortho* isomer of the triaryl phosphates is neurotoxic. In North

America, there has been a strong trend away from the neurotoxic tricresyl phosphate additives. However, some of the additives and possibly metabolites produced by microbial degradation can be endocrine disruptors and can target reproductive organs (Somkuti *et al.*, 1987; Latendresse *et al.*, 1993, 1994a). Lesions in the adrenal cortex and ovary have been reported for tricresyl phosphate and butylated triphenyl phosphate. Tricresyl phosphate caused lesions in the testicle, but testicular lesions were not observed with butylated triphenyl phosphate. Both tricresyl phosphate and butylated triphenyl phosphate decreased reproductive performance in male and female rats.

The use of nonpesticide neurotoxic organophosphate esters has been reduced in North America, but these compounds may be buried in disposal sumps (Table 61.2). The neurotoxicity is limited to the *ortho* isomer. Natural gas compressor stations use nonpesticide organophosphate esters to prevent foaming of lubricating oils (Coppock *et al.*, 1995a). Phosphate esters have multiple uses in the petroleum industry, and they have been used in high-performance lubricants. The trivial chemical names describing the industrial grade

generally refer to complex chemical mixtures of these compounds (Dollahite and Pierce, 1969; Beck *et al.*, 1977; Sugden, 1981). For the phosphate esters used in industrial applications, the majority of the individual compounds have incomplete toxicological data (Coppock *et al.*, 1995a). Studies relating the chemical structure of individual tricresol phosphate compounds to neurotoxicity have allowed structural grouping of many of the neurotoxic compounds (Johannsen *et al.*, 1977; Sprague and Castles, 1987; Abou-Donia and Gupta, 1994). The neurotoxicity of organophosphate esters is related to the inhibition of cholinesterases, and the malady produced by inadvertent exposure to triaryl phosphate group (TAP) is known as organophosphate-induced delayed neurotoxicity (Metcalf, 1984). There is wide variation in species sensitivity and the effect of age on sensitivity within species (Abou-Donia and Gupta, 1994). The neurotoxicology of the TAP group of compounds has been described in cattle (Dollahite and Pierce, 1969; Nicholson, 1974; Julian *et al.*, 1976; Beck *et al.*, 1977; Sugden, 1981; Prantner and Sosalla, 1993), other livestock species (Wilson *et al.*, 1954; Dollahite and Pierce, 1969), and chickens (Hixson, 1984). Humans are

TABLE 61.2 Clinical signs of delayed neurotoxicity in cattle

Source	Time sequence <sup>a</sup>	Clinical signs	Reference
Waste hydraulic oil	12 days	Diarrhea	Julian <i>et al.</i> (1976)
	20 days	Posterior weakness, knuckling at fetlocks, ataxia, difficulty in rising, and dog-sitting while attempting to rise	
	20+ days	Diarrhea, coughing, ataxia, difficulty turning, knuckling and buckling of rear limbs, unable to rise but could walk on knees, and decreased sensory and motor response in rear limbs	
	34+ days	Increased severity of clinical signs, incoordination progressing to front legs, standing in a crouched position, muscular wasting, dribbling urine, tail raised, coughing, dyspnea after attempting to rise, and death (14/50)	
Waste oil	NS	Roaring sounds	Prantner and Sosalla (1993)
	2 days	Ataxia of hind limbs and knuckling over at metatarsophalangeal joints	
	42 days	Second heifer, with signs same as for first heifer	
Compressor sump water	7 days	Third heifer, with ataxia, dysuria, polyuria, and dyspnea	Beck <i>et al.</i> (1977)
	42 days	Fourth heifer, with clinical signs same as for third heifer	
	NS	Cows mute when separated from calves	
	7 days	Knuckling of fetlocks, dyspnea, and coughing

<sup>a</sup>After exposure.

also susceptible to TAPs (Craig and Barth, 1999). The most common source of TAPs in livestock poisonings results from their use as additives in lubricating and hydraulic oils operating under high pressure and temperature. Cattle will voluntarily ingest water and feed-stuffs adulterated with TAP (Dollahite and Pierce, 1969; Nicholson, 1974; Beck *et al.*, 1977; Prantner and Sosalla, 1993). Oil field-related exposures of cattle to TAP have been primarily from compressor oils and hydraulic fluids (Dollahite and Pierce, 1969; Beck *et al.*, 1977; Coppock *et al.*, 1995a). Compressor lubricating oils in recycled barrels used to store wet molasses were the source of TAP in an incident in which cattle were poisoned (Nicholson, 1974). An undetermined source of waste oil used to lubricate a feed bunk chain was the source of TAP in a poisoning incident in heifers (Prantner and Sosalla, 1993). Waste oil used to treat ringworm was the source of TAP poisoning in a herd of cattle (Julian *et al.*, 1976). Sump pits containing these substances can be uncovered, and cattle, if they have access, may ingest them.

### Antihydrates and antifreezes

Antihydrates and antifreezes are used in the oil fields. Large quantities of methanol are used by the oil and gas industry, and cattle have been poisoned by these sources (Edwards *et al.*, 1979; Rousseaux *et al.*, 1982). Methanol is used to prevent freezing of water in pipes and to prevent hydrate formation in gas wells and pipelines. Intoxication of cattle by methanol has been reported. A herd of 600 cows had access to methanol barrels stored on a lease, and 2 cows were found dead. Manure accumulation behind the cows was taken as evidence that the cows had been recumbent for some time before death (Rousseaux *et al.*, 1982). Rumen contents from the 2 dead cows contained 370 mg of methanol/100 mL of rumen fluid. In another incident, 12/15 cows were found dead or in a moribund condition (Sesevicka *et al.*, 1979). Clinical signs observed were ataxia, decreased rate and depth of respiration, frequent chewing motions, impaired vision, and hypoaesthesia to nociceptive stimuli. These heifers had access to a pit that received wastewater from a gas processing plant. Clinical signs of experimentally induced methanol poisoning in cattle were similar to those reported for field exposures (Fritz and Coppock, 1992). Large quantities of diethylene glycol (DEG) are used in oil and gas operations (Edwards *et al.*, 1979). Research has shown that cattle are a species sensitive to DEG (Fritz and Coppock, 1992; Khan *et al.*, 1992). A dose of 1.5 mL/kg BW is fatal to a cow. Diethylene glycol is toxic to the eye, liver, kidney, and nervous system. Diethylene glycol induced ocular changes that are similar in appearance to those of pinkeye. Diethylene glycol causes a unique lace-like hypertrophy of the

perineuronal amphicytes in the gasserian ganglia in cattle. This lesion has not been reported in laboratory animals. Other glycols are used as antifreezes in oil and gas production.

### Chromate

Cattle are exposed to environmental chromates from oil field sources (Reagor and McDonald, 1980). Gross pathological findings in a calf (8 months old) were icterus, tracheal froth, excessive pleural fluid, and petechiae over the pleura. The intestinal contents were black and mucus covered. Edema and hemorrhage were observed in the mesentery and omentum. Hepatomegaly, yellowing of the liver, and edema of the gallbladder were observed. Histopathological observations included diffuse hepatocellular swelling, vacuolation of hepatocytes, inspissation of bile, and moderate biliary hyperplasia. The kidneys were pale, and hemoglobinuric vacuolation was observed in the cortical tubular epithelium. Proteinaceous exudate was observed in the lung, and epicardial hemorrhages were observed. Chromium concentration in the liver was 14.8 ppm.

## GREASE AND MOTOR OIL

Lithium (Li) intoxication in cattle from Li grease has been reported. Wallace and Blodgett (1996) reported Li poisoning in one cow after the animal consumed Li grease, and Johnson *et al.* (1980) reported on Li poisoning in 19 of 90 animals. In both incidents, the source of Li grease was discarded drums that had been used previously for transporting and storing grease. In the incident reported by Wallace and Blodgett, the cow was euthanized, and in the incident reported by Johnson *et al.*, all 19 animals died. In the animals that consumed Li grease, clinical signs included muscular tremors, ataxia, stiffness, apparent disorientation, ptialism, diarrhea, rapid respiration, and periodic seizure-like activity. The concentrations of Li in grease for the incidents reported were 2050 and 1250 µg of Li/g of grease, respectively. Clinicopathological findings (1 cow) included leukopenia, lymphopenia, and hyperfibrinogenemia (Wallace and Blodgett, 1996). The parameters of protein, cytology, and glucose in cerebral spinal fluid were normal. An oral dosing study with Li has been done in cattle (Johnson *et al.*, 1980). Cattle were administered single oral doses per gavage of 250, 500, or 700 mg of LiCl/kg BW. The LiCl was in water (qs to dissolve the Li) plus an equal volume of water to rinse the stomach tube. Clinical signs were reported (Table 61.3). The most consistent finding

TABLE 61.3 Summary of clinical signs of Li intoxication in cattle

Oral dose (mg/kg)	Time	Clinical signs
250 (4) <sup>a</sup>	2–6 h	Ptyalism
	4–6 h	Depression, anorexia, and diarrhea
	72 h	Diarrhea
	9 days	Recovered
500 (5)	3–4 h	Ptyalism (lasted for 4–6 h)
	After 4–6 h	Depression, anorexia, hypodipsia, anuria, and diarrhea
	7 days	4 animals died
	11 days	1 animal died
700 (4)	2 h	Ptyalism (continued for 4–6 h)
	After 2 h	Depression, anorexia, hypodipsia, anuria, ataxia, and severe diarrhea
	8 h to 7 days	Deaths occurred

<sup>a</sup>Numbers in parentheses indicate the number of cows in the trial.  
Data from Johnson *et al.* (1980).

at necropsy was gastroenteritis of varying severity. Histopathological findings were congestion of the gastrointestinal tract. Lesions in the liver included cloudy swelling, edema, and cirrhosis in the portal triad areas. Renal lesions included cloudy swelling of the proximal tubular cells and a mild interstitial nephritis. Lithium can also be present in process water.

Grease and motor oil generally contain additives and other metallic substances that provide water resistance, increase lubrication under high pressure, and provide other desirable properties. Grease containing lead has excellent water-repellent properties. Lead grease is also a hazard to livestock. Molybdenum is added to grease to improve lubrication under extreme pressure. Motor oil contains additives to prevent foaming, keep carbon deposits in suspension, and reduce friction and wear of parts at high temperatures. Motor oil contains additives to improve lubrication under low and high temperatures, pour-point improvers, and antioxidants. Synthetic oils can contain molybdenum and surfactants. Antiwear additives such as zinc dialkyldithiophosphate compounds and derivatives are added to lubricants to reduce friction. Micronized metals can be added to lubricating oils. Many additives are mixtures of substances, and most companies closely guard their intellectual property.

## TOXICOLOGY OF CRUDE AND REFINED PETROLEUM

Ruminants are attracted to and ingest petroleum. They like it and ingest it. The most important short-term risk

TABLE 61.4 Chemical characteristics of crude oils used in the Rowe and Bystrom studies

Fraction	Pembina crude <sup>a,b</sup>	Texas sweet (%) <sup>c</sup>	Texas sour (%) <sup>c</sup>
Light gasoline	NA	14.2	9.6
Total gasoline or total naphtha	22.1%	43.0	31.6
Kerosene	15.3%	22.3	4.7
Lubricating	NA	8.8	16.8
Sulfur	0.24%	<0.1	1.5
Nitrogen	0.1%	0.083	0.074

for ingestion of crude oil, diesel oil, and kerosene is chemical pneumonia. The risk of developing pneumonia is greatly increased by the occurrence of emesis or nervous system dysfunction. Nervous system dysfunction is caused by volatile hydrocarbons. Weathering of crude petroleum reduces the occurrence of signs of nervous system dysfunction. Milk is tainted after the ingestion of crude and refined petroleum.

## Experimental studies

The toxicology of petroleum has been reported for experimental studies. Rowe and colleagues (Rowe, 1972; Rowe *et al.*, 1973) found that sweet crude oil was more toxic in cattle than was sour crude oil (oil that contains sulfur) (Table 61.4). Administration of 8 mL of sweet crude oil/kg BW/day caused death within 7–14 days in 4 of 5 calves. For the same dose of sour crude oil, 5 of 5 calves died between days 16 and 24; for kerosene, 5 of 5 calves died between days 9 and 23. Administration of 37 mL of sweet crude oil/kg BW was fatal within a few minutes. The majority of the surviving animals had pneumonia.

Bystrom (1989) studied the acute effects of crude oil in cattle. The dosage levels (administered per gavage) were 20, 40, 60, or 80 mL of sweet crude oil/kg BW, or 80 mL of potable water/kg BW. The analytical characterization of the oil is given in Table 61.4. Following exposure, daily mean rectal body temperatures were normal. Ruminal motility was decreased after animals were dosed with oil and slowly increased to pretreatment values by day 8. Vomiting was not observed in the animals dosed with water. Vomiting occurred in 10 of 12 of the animals

dosed with oil, and in some animals, vomiting was characterized by a projectile expulsion of oil. Other animals had oil dripping from their nostrils. Emesis recurred after forage or water was ingested. Ruminant tympanites was observed in the majority of the animals but did not require medical intervention. Neurological abnormalities were not observed in control animals. Central nervous signs expressed by nystagmus, muscular tremors, and petit mal-like seizures were observed in treated animals. Depression was the most common clinical sign observed. These effects were attributed to the anesthetic-like effects of the volatile hydrocarbons. The neurological effects contributed to aspiration pneumonia. Oil in feces was determined by gas chromatographic methods. Oil was found in feces at 23h after dosing for the 20- and 40-mL/kg groups, at 7–31h for the 60-mL/kg group, and at 5–19h for the 80-mL/kg group. Oil was not detected in feces from the control animals. Using head-space (space between the liquid and stopper) analysis, it was demonstrated that volatile constituents from the oil were present in blood. *N*-heptane was used as a representative hydrocarbon. Semiquantitative values for total light naphtha were estimated to be as high as 10mg/L of blood. Aspiration of oil into the lungs increased the levels of *N*-heptane in the blood.

Considerable variation in the dose–response of cattle to mineral petroleum has been reported. These effects can be due to the presence of surfactants or emulsifiers and other additives in refined petroleum. A 200-mL single oral dose of odorless kerosene administered to a mature dairy cow caused a 90.3% reduction in dry matter intake, and the same dose of Stanvac Odorless Solvent caused a 42.5% reduction in dry matter intake (Reid, 1957). These effects were considered to be in remission by day 3 of the study. Emulsification of kerosene with a non-ionic surfactant decreased the interval between exposure and the onset of effects. Similar findings were observed when kerosene was placed directly into the omasum. Fistulation of the rumen did not alter the response to kerosene or solvent.

Exposure to petroleum can reduce body stores of fat-soluble vitamins. McDowall *et al.* (1957) administered 75mL of heavy liquid paraffin/cow/day by drench for 26 days. A 40% reduction in blood carotene occurred over 16 days, and a 20% reduction in blood vitamin A ester and a 40% reduction in tocopherol (vitamin E) were also observed. After cessation of treatment, 21 days were required for recovery to pre-exposure levels.

## Ingestion of petroleum

In the scientific literature, there are numerous reports of cattle and other animals voluntarily ingesting petroleum and other oil field substances (Coppock *et al.*,

1986a, 1995b). Cattle are attracted to and will ingest several gallons of petroleum (Monlux *et al.*, 1971; Oehme, 1977). Deaths have occurred after cattle drank tractor paraffin and vaporizing oil (Eaton, 1943). Heifers drank gasoline (Albert and Ramey, 1964), and Messerli (1969) reported that cattle greedily ingested diesel oil flowing from a storage tank. Cattle have drunk from petroleum puddles near a tank battery, from slush pits, and from puddles of volatile petroleum and petroleum distillate (Edwards *et al.*, 1979). Cattle have consumed crude oil spilled by a pipeline break and have drunk from puddles of road oil after it was applied for dust suppression (Coale, 1947; Bumstead, 1949). Cattle will drink used motor oil (Gardner, 1977) and will also ingest petroleum-contaminated forage (Stober, 1962; Beck *et al.*, 1977). An entire herd of heifers was irreversibly poisoned by ingesting water from a stream that had been previously contaminated with aviation turbine fuel (Barber *et al.*, 1987). Monlux *et al.* (1971) reported that the majority of animals avoid oil but that, in some instances, the entire herd, especially feeder calves, is attracted to oil. Cattle have ingested sump oil with adverse effects on health (Ballantyne, 1950, 1955). Other ruminant species also ingest petroleum. Sheep have ingested Bunker “C” fuel oil (a residual fuel oil) following the sinking of a tanker ship (MacIntyre, 1970). Ingestion of surface water contaminated with extrusions by rainwater of natural gas condensate has caused fatalities in sheep (Adler *et al.*, 1992). Goats voluntarily ingested kerosene (Pathan, 1961). In Iran, goats ingested diesel fuel leaking from an overturned truck tanker (Toofanian *et al.*, 1979).

## Experimental studies on ingestion of petroleum

Experimental studies on the ingestion of crude oil by cattle have been reported (Rowe, 1972; Rowe *et al.*, 1973; Coppock *et al.*, 1992). Calves were observed to drink sweet and sour crude petroleum. After water had been withheld for 48h, calves drank 4L of either a sweet or a sour crude oil, but they would not repeat the ingestion of crude oil after water had been withheld for a total of 96h. Two of the calves that drank oil had been administered per gavage kerosene in a previous study. Calves that were not water deprived did not drink oil. These findings suggest that cattle may acquire some aversion to drinking crude petroleum, and water deprivation can be a factor in the ingestion of kerosene. An experimental study demonstrated that cows on a balanced diet and provided water *ad libitum* are attracted to crude mineral petroleum and will ingest it (Coppock *et al.*, 1992). In a study on voluntary ingestion of crude oil, a stall was designed to minimize competition at the oil source. All of the animals explored the oil, and 5 of 10 animals ingested oil. For 3 of 4 animals that drank oil,

TABLE 61.5 Clinical signs of acute petroleum poisoning in cattle

Acute signs (<24h)	Subacute signs (>24h)	Chronic signs (>30 days)
Ruminal tympanites <sup>a</sup>	Depression	Lethargy
Emesis	Pneumonia	Varying degrees of anorexia
Postural weakness	Anorexia	Loss of condition
Ataxia and incoordination	Constipation	Impaired reproductive performance
Seizures	Coughing	Chronic cough
Hyperthermia	Ileus	Abortion
Dyspnea	Recumbency	Laminitis
Bloody diarrhea	Ruminal atony	Loss of body weight
Strong petroleum-like odor on breath; feces have odor of petroleum	Abortion	Pain – hardware-like signs
Ruminal atony	Loss of weight	
Depression	Sweet petroleum-like odor to breath and feces; feces have petroleum odor	
	Lethargy	

<sup>a</sup>Ruminal tympanites is not a consistent finding.

ingestion occurred most frequently in the first few days during which the oil was available. The most frequent method of ingesting oil was by licking; the cyclic pattern suggested that cattle go on oil-licking “binges” in a substance abuse pattern. The neurochemical reasons for the attraction of cattle to oil are not known. This study showed that cattle provided water *ad libitum* and receiving a balanced diet do ingest crude oil.

### Clinical observations and findings

Varied clinical signs have been observed in field incidents of petroleum poisoning (Table 61.5). A herd of 58 yearling steers had access to crude petroleum distillate (condensate) on an oil-lease property (Edwards and Zinn, 1979). Following oral exposure, 17 animals became sick and 9 died. The sick cattle had petroleum distillate dripping from the nostrils, and it was present in their feces; they also had petroleum on their tails and rear quarters. Surviving animals had varied signs, including anorexia and weight loss. Some of the more severely affected animals died. Edwards and Zinn also described clinical signs in 18 of 135 animals that had access to a sump pit. The surviving animals lost weight and were unthrifty (“poor-doers”). These authors also reported that of 200 steers with access to petroleum in puddles, 12 were found dead and 13 died 24 h later. Oehme (1977) attributed abortions to ingestion of petroleum products. Loss of body condition can also result from petroleum ingestion-linked chronic pneumonia and pleural adhesions. Clinical evidence of pain can be associated with pleural adhesions (signs similar to those of hardware disease). Cattle attracted to an area saturated with condensate can have laminitis-like clinical signs.

A herd in Alberta, Canada, had access to sump oil (Ballantyne, 1950). A 545-kg cow, representative of a malady observed in 20 other cows from a large herd, was necropsied. After ingestion of oil, this cow had a reduction in body weight. Necropsy findings were as follows: there was visible oil in the rumen, the mucous membranes of the abomasum were stained black, and areas of inflammation were observed in the gut. There was 213 mL of oil/L of rumen contents. In another report, cattle drank from a pool of oil (Bumstead, 1949). Two animals died, and all of the animals that had wandered into the pool of oil showed clinical signs of intoxication. One heifer had severe enteritis, was dehydrated, and had cachexia. All of the animals treated by the veterinarian were considered to have made a complete recovery, which was attributed to treatment that rapidly removed oil from the digestive tract and prophylactic treatment with an antimicrobial chemotherapeutic. In another report, 5 dairy cows drank crude oil that had escaped from a broken pipeline. All 5 of the animals were sold 90 days later because of lost productivity (Coale, 1947).

Gibson and Linzell (1948) reported that dairy cows drank petroleum after 5 gallons (23 L) was mistakenly dumped in a water trough. Clinical signs in 6 of 8 cows were central nervous system (CNS) depression including coma, coughing, salivating, head shaking, hypothermia, and petroleum odor on respired air and milk. The diesel-like odor on the breath and in the milk persisted for 5 days. Three animals died at 12, 24, and 48 h, respectively, after exposure. During the interval between exposure and death, all of the animals ate and ruminated but were dull in temperament and were constipated. Forty-eight hours after ingestion, 2 cows had abnormal respiratory sounds, which in 1 cow persisted

for 14 days. The pathological findings were chemical pneumonia and evidence of inflammation of the mammary gland. Another author reported clinical signs of vomiting and death after a lactating Shorthorn animal ingested approximately 1 gallon (4.5L) of tractor paraffin (Eaton, 1943). Twenty-four hours after ingesting tractor paraffin, a 3-year-old bullock had signs of marked excitement to wildness, blindness, and incoordination. Clinical signs of anorexia and constipation were reported after cattle ingested tractor vaporizing oil (low grade of kerosene) (Parker and Williamson, 1951). Pathological findings were fatty changes in the liver, degeneration of the kidney, and multiple small hemorrhages in the lungs. Twenty-four dairy cattle ingested diesel oil from a storage tank valve that was opened, possibly by the cattle (Messerli, 1969). Clinical signs of intoxication were observed in 9 of 24 cows 30h later, and 4 of 24 cows were considered to be seriously affected. Milk from all the cows had a diesel odor. From this herd, a Brown Swiss cow in critical condition was examined in detail. Clinical signs observed in the cow were elevated body temperature, bradycardia, decreased appetite, decreased peristaltic ruminal movements, diarrhea, muscular weakness, and decreased milk production. Eight days after ingesting diesel, swelling of the rear fetlocks was observed. Eighteen days after ingesting oil, the herd milk production was diminished by 75%; 2 months later, unsteady movements were observed, and after an unspecified interval, the cow regained her health. Three of the other seriously affected animals required 1 month for recovery and had retarded growth for a substantially longer interval. The feces had a diesel odor for 5 days.

Peterson (1963) reported that after a herd of cattle had access to heating oil-contaminated water for 12h, two cows showed remarkable clinical signs. One cow was pyrexia (41.1°C) and had severe dyspnea. The body temperature of the second cow was 38.8°C, and there was clinical evidence of abdominal pain. The first cow was treated with intravenous antibiotics and laxatives; she passed fuel oil in her feces and made a complete recovery. The second cow received similar treatment, did not eat for 2 weeks, developed septic metritis followed by pneumonia, and subsequently died. Poor health and an abnormal liver in a heifer were attributed to her drinking gasoline 15 months previously (Albert and Ramey, 1964). Immunosuppression could have occurred, and no mention was made of plumbism.

Barber and colleagues (1987) reported an environmental incident with aviation turbine fuel. Fifty-one heifers 12 to 18 months old were exposed to water in a stream that had been contaminated with aviation turbine fuel. The duration of exposure was not determined and, when discovered, the contaminated waterway was immediately fenced and the heifers

were provided an alternative source of drinking water. Observations at the initial appointment were 2 heifers dead and 5 animals with signs of ataxia. During a 3-week interval, 8 heifers died or were euthanized *in extremis*. Animals that survived were dull (CNS depression), did not show interest in strangers walking about the field, and had remarkable weight loss, and increased respiratory rate was observed in some animals. Six weeks after the initial examination, 41 of the surviving animals appeared unhealthy. At 121 days after the initial examination, the heifers were compared to siblings and were found to have lost 50–100kg. Because of apparent chronic, poor health, 41 of the heifers were slaughtered approximately 124 days after the initial exposure. One heifer died during transport to slaughter. After slaughter, the animals were submitted for pathological examination. All of the heifers were poorly fleshed for their skeletal size. Some of the animals had liver flukes, but lungworms were not observed. Essentially all of the lungs were considered to be grossly abnormal, as exemplified by enlargement and grayish-blue areas of varying size, and had firm consistency. However, histopathological abnormalities were not observed in the lungs and kidneys.

### Dermal toxicity of petroleum

Pesticides applied to cattle using “cattle oilers” are often diluted with diesel oil and kerosene. Petroleum distillates are sometimes used as vehicles for fly sprays. Diesel fuel was considered to be the cause of a severe skin reaction to fly spray (Edwards and Niles, 1981). The abdomens and legs of the cows were sprayed each time the cows entered the barn, and when the cows exited the barn, the same mixture was rubbed on their backs. The fly spray was a mixture of 3.8L of proprietary fly spray mixed with 53L of diesel fuel. Erythema of the skin, swelling of the carpus, and varying severity of edema were observed on the front legs between the elbow and fetlocks. Skin on the back, rear legs, and udder was not affected. The authors postulated that washing before milking protected the udder and rear legs. The fly spray–diesel mixture produced similar lesions on the backs of guinea pigs. Treatment consisted of washing the front legs, application of scarlet oil, and discontinuing the use of the fly spray mixture. Using a different source of diesel fuel for diluting the fly spray was considered significant in causing the dermatitis. The causative agent in the diesel fuel was not identified. The mixture of pesticide and kerosene and diesel oil can increase the rate of absorption of pesticide. The diesel oil–pesticide mixture can be spilled from overturned oilers. Cattle were attracted to soil that had been saturated with crude condensate. Puddles of condensate were observed in the

cattle tracks. Clinical signs of laminitis were observed in many of the animals in this herd. It is assumed that the petroleum was absorbed through the hoof wall and caused inflammation.

### Biochemical toxicology

Studies on the biochemical toxicology of crude and refined petroleum have been performed (Khan *et al.*, 1989). Initial studies showed that Pembina Cardium crude oil (PCCO) increased hepatic microsomal protein cytochrome P450 content and the activities of NADPH-cytochrome *c* reductase, aryl hydrocarbon hydroxylase (AHH), 7-ethoxycoumarin-*O*-deethylase (ECOD), and cytosolic glutathione transferase. The clinicopathologic and biochemical effects of PCCO or commercial diesel fuel (CDF-2) were studied in rats (Khan *et al.*, 2001). On days 1, 3, 5, and 8, specified dosages of the control vehicle, methylcellulose (MC) (1.25 mL/kg), PCCO (0.25–1.25 mL/kg BW), or CDF-2 (1.25 mL/kg BW) were given per gavage. No overt signs of intoxication were observed. Liver somatic index increased in rats exposed to 1.25 mL/kg doses of PCCO and CDF-2. Hematology and serum chemistry parameters were not significantly increased. The PCCO- and CDF-2-exposed groups had a significant increase in the hepatic activity of ethoxyresorufin-*O*-deethylase (EROD). In PCCO-exposed rats, the induction of EROD increased with dose. Dose-related increases occurred in hepatic activities of AHH, ECOD, glutathione transferase, and NADPH-catalyzed microsomal lipid peroxidation. The renal activity of ECOD was significantly increased. Studies in rats have shown that these enzymes downregulate in a temporal manner after per gavage exposure to low levels of PCCO are discontinued (Khan *et al.*, 2002). Cattle were administered single oral doses of PCCO at 16.7, 33.4, and 67.4 g/kg BW or 80 g water/kg BW (control) (Khan *et al.*, 1996). Cattle from each treatment group were sacrificed on post-treatment day 7 or 30, and biochemical parameters were assayed in liver, lungs, and kidney cortex. On day 7, the PCCO-treated groups showed marked alterations from the control group in hepatic cytochrome P450 and in the activities of AHH and ECOD. There was a 100% increase in hepatic cytochrome P450. AHH activity was increased in all tissues. The enzyme activity was increased greater than 5000% in kidney cortex, greater than 500% in liver, and greater than 250% in lungs. The activity of ECOD was increased greater than 1300% in kidney cortex, slightly increased (20–30%) in liver, and decreased (>80%) in the lung parenchyma. The activities of respiratory chain enzymes were not changed in any tissues. By day 30, the alterations in cytochrome P450, AHH, and ECOD observed on day 7 were markedly reversed.

## VETERINARY MEDICAL AND PESTICIDE USES OF PETROLEUM

### White oils

Mineral oils are purified and used for medical purposes and added to human foodstuffs and animal feedstuffs (IARC, 1984). The mineral oils are highly refined naphthenic or paraffinic distillates. The unsaturated compounds, including aromatics that add color and taste, and sulfur compounds have been removed. Treatment methods including solvent extraction and steeping with strong sulfuric acid can be used as well as adsorption with clay minerals. Alternatively, hydrogenation can be used. To meet U.S. Pharmacopeia (USP) standards, mineral oils have a very low sulfur and aromatic and polyaromatic hydrocarbon content. Mineral oils are used in the food industry, used as lubricants in manufacturing of human foodstuffs, directly added to foodstuffs, and used as anti-bloat oils and a pharmaceutical. Purified mineral oils are mixed with surfactants (pasture spray oil) and sprayed on alfalfa (lucerne) forage before grazing as a prophylactic for bloat in cattle. Food-grade mineral oils are used as horticultural oils to control pests (Beattie *et al.*, 2002).

### Kerosene and diesel oils

There is historical record of various mineral petroleum fractions being used as veterinary medicaments. Lamp paraffin (kerosene) and other kerosene-like products were used as a veterinary medicament for treating animals with intestinal helminths, frothy bloat, and diarrhea, and crude oil was used as an aperient. The unpredictable adverse reactions of orally administered kerosene are anorexia, ptyalism, indigestion, irritation of the digestive tract, respiratory difficulties, and death. These effects were attributed to its variability in chemical composition (Reid, 1957; Stober, 1962). Clinical signs have been described for a cow that was drenched with lamp oil. In the first incident (Shenton, 1937), the owner administered 1 pint (0.57 L) of paraffin oil to control bloat. Twenty-four hours later, the cow was examined and a rumen cannula inserted. Forty-eight hours later, there was an absence of rumen motility, and the cow would vomit after drinking water. On day 3, a stomach tube was passed, and gas and water were removed from the rumen. On day 4, the cow drank gruel and water, and it died on day 5. Necropsy findings were severe inflammation and necrosis of the esophagus, inflammation of the abomasum, and the smell of paraffin in the ingesta. Munch (1956) advised that because of unpredictable adverse effects, crude oil should not be

used as a laxative for cattle. Exposure to mineral oil can deplete fat-soluble vitamins. McDowall (1957) administered per gavage 75 mL of heavy paraffin/cow/day by drench for 26 days. A 40% reduction in blood carotene occurred over 16 days, and a 20% reduction in blood vitamin A ester and a 40% reduction in vitamin E were also observed. After cessation of treatment, 21 days were required for recovery to pre-exposure levels.

## SOUR GAS

Sour gas is natural gas that contains  $\text{H}_2\text{S}$ , other sulfur compounds, methane, and other petroleum hydrocarbons. In addition to the toxicity of  $\text{H}_2\text{S}$  and other sulfur compounds, sour gas is extremely irritating to the eyes and respiratory tract. Sour gas wells are drilled and produced for natural gas (methane), sulfur, and liquids (a variety of commercially valuable hydrocarbons). The crude sour gas is collected in a pipeline system ending at the sour gas plant. At this facility, production water, liquids, and the sulfur are removed. Removal of sulfur compounds is referred to by the petroleum industry as the sweetening process. Release of sour gas and other sour products occurs as fugitive emissions, pipeline breaks, wellhead incidents, and from unlit flare stacks. Sour gas is a complex mixture of chemicals, and the chemical composition varies from well to well. It is likely that indexing the toxicity of sour gas on  $\text{H}_2\text{S}$  levels underestimates the toxicology. Stress from irritation of mucous membranes and other factors can increase the risk of infectious pneumonia in cattle and horses.

### Sour gas well blowouts

Sour gas well blowouts constitute a unique hazard to livestock. In the blowout incidents that have been reported in the literature, cattle were confined by fences, corrals, etc. and generally could not escape the airborne emissions. Ranchers and their families may have been under emergency evacuation order and forced to leave their cattle and other livestock unattended. The evacuation alone can cause major disruptions in animal husbandry. Sour gas is heavier than air and settles into low areas, especially during cool temperatures. Low areas tend to be sheltered from the wind, and less mixing of the air occurs. The toxic effects of sour gas observed in these incidents are summarized in Table 61.6. Details of the incidents are provided.

During rework operations of a sour gas well in western Canada, a blowout occurred (EPS, 1973). The rate of flow and  $\text{H}_2\text{S}$  concentrations were estimated at  $11.6 \text{ ft}^3/\text{s}$

and 4–8%, respectively. Ideal conditions for the dispersal of gas were reported to have existed during the blowout. Cattle in one herd were reported to have a watery discharge from eyes and nostrils. The Veterinary Diagnostic Laboratory examined cattle from six farms. The diagnosis was pneumonia.

Cattle were studied in western Canada after a sour gas well blowout (Lodgepole blowout) that occurred in 1982 (October 17 to December 23). The duration of the blowout was essentially 67 days, and the estimated flow rate was greater than  $4.2 \times 10^6 \text{ m}^3/\text{day}$ , giving an estimated release of 900–1400 metric tons of elemental sulfur equivalent/day. The well was ignited at 14:07h on November 1, 1982, and burned until November 17. The well was ignited again at 12:53h on November 25, 1982, and burned until it was extinguished during the capping process. The well was not on fire for 27 days, and it was ignited for approximately 40 days. Two human fatalities occurred during attempts to control the well. There were differences of opinion concerning the harmful effects of emissions from the Lodgepole well. Round (1992) reported clinical signs of ocular and respiratory irritation that was locally described as “red-eye syndrome.” Improvement of cattle with the red-eye syndrome was observed immediately after the well was capped. The well emissions were considered to be suspect in causing abortions, and infectious causes of abortions were not identified. The number of aborted fetuses and diagnostic trends were reviewed for the interval before, during, and after the Lodgepole blowout (Klavano and Christian, 1992). Concerning submissions sent to the Animal Health Laboratory, the Lodgepole blowout did not result in a change in the number of fetuses submitted to the laboratory or the diagnostic trends established for aborted fetuses. A study was done on the attitudes and opinions of livestock producers regarding the long-term effects in cattle of the emissions from the Lodgepole blowout (Harris, 1992). The producer-based observations were on 1700 beef and 40 dairy cows. Problems associated with trace mineral deficiencies, including change in hair color, were more prevalent among exposed cattle; complaints of blowout-associated maladies in cattle increased with increasing proximity to the well. Complaints of blowout-associated maladies also were more common for cattle located in low-lying areas. Concerns regarding low birth weights were more common for producers who had not recorded birth weights. Other problems included difficult calving due to *inertia uteri*, calves born with deformed feet, and calves that were “poor-doers.” Farmers complained of reduced growth in replacement heifers. The study included one dairy producer. Lactating cows exposed to the blowout gas had a 20% reduction in milk production. There was no report of decreased milk production in cows that freshened after the blowout. The calving interval

TABLE 61.6 Summary of observed effects of blowout emissions in cattle

Blowout	Observations	References
Canada	Watery discharge from eyes and nostrils; pneumonia was observed.	EPS (1973)
Canada, Lodgepole blowout	Ocular and respiratory irritation, abortions, and other reproductive problems.	Round (1992)
	Number of aborted fetuses and diagnostic trends did not change for the Provincial Laboratory (Edmonton) during and after the blowout.	Klavano and Christian (1992)
	Maladies in cattle increased with decreasing distance from the well and were increased in geographically low areas; problems associated with trace mineral deficiency were observed, as were changes in hair color; <i>inertia uteri</i> , calves were born with deformed feet; calves had failure to thrive, decreased growth of replacement heifers, possible decreased birth weights, and 20% reduction in milk production by dairy cows; calving interval increased; with increased interval from exposure, the herd returned to normal.	Harris (1992)
	Significant reduction in weaning weights of calves exposed as cow-calf pairs.	Whitelock (1992)
	Possible association with exposure to well emissions were as follows: Physical examinations were within the expected normal variation; pathological findings were of varied diagnosis and were not considered to be unique; three calves from these cows raised at the laboratory grew at average to above average rates; parameters used may not have been sensitive enough to detect irreversible toxicological effects; and the owner may have been biased in his evaluation of long-term effects.	Church (1992)
Mississippi (USA)	Irritation of the eyes and respiratory tract; respiratory distress; clinically affected 9 months later.	Edwards (1992)
Canada, Drummond	Investigation team concluded that reasonable evidence may have existed for transient respiratory disease, extended feeding time to finish exposed feedlot cattle. Possible for transient exercise intolerance in horses to be linked to exposure to sour gas. Probable links to eye and respiratory irritation in cattle and horses.	Anonymous (1986)
Canada, multiphase pipeline leak	Ocular and nasal irritation; evidence of immune and nervous system dysfunction; aggressive behavior in cows; <i>in estrus</i> behavior of pregnant cows; above average mortalities in cows and calves; calves lacked sucking instinct; cows failed to nurture newborn calves; lymphoid and thyroid hypoplasia and putative endocrine disruption.	Mostrom <i>et al.</i> (1995), Mostrom and Campbell (1996)

increased to 13.9 months during 1983 and then returned to 11.8 months the subsequent year. The owner considered his herd to have been affected by the blowout emissions and then returned to normal.

Whitelock (1992) reported his observations in cattle attributed to the emissions from the Lodgepole blowout. He observed a statistically significant reduction in weaning weights after exposure of cow-calf pairs and weaned calves to emissions from the Lodgepole well. Church (1992) interviewed farmers and evaluated cattle for toxic effects. In a 118-cow herd of purebred Angus cattle exposed to the well emissions, eight parameters may have been related to exposure to blowout emissions: (1) average decrease of 15 pounds (7kg) in birth weight, (2) a 100-pound (45-kg) decrease in weaning weights, (3) a 4.6% increase in birth defects or stillborn calves, (4) a 9.5% increase in abortions, (5) loss of hair color (fading and graying), (6) decreased growth and milking ability of heifers born in 1983, (7) breeding problems such as abnormal cycling, and (8) a 23% increase in culling rate. Three of 10 control herds had two of the problems listed for the exposed herd. One of the farmers requested that his cows be evaluated by laboratory procedures (Church, 1992). Six cows, considered by the owner to be the worst

affected, were examined in 1986. The laboratory findings were as follows: (1) three calves from these cows raised at the laboratory grew at average to above average rates, (2) findings of physical examinations were within the expected normal variation, (3) pathological findings were of varied diagnosis and were not considered to be unique, (4) parameters used may not have been sensitive enough to detect irreversible toxicological effects, and (5) the owner may have been biased in his evaluation of long-term effects.

Edwards (1992) described the impact of emissions in cattle from a sour gas well blowout that occurred in 1985 in the southern United States. The well blew for 72 days at a pressure of 1340 kg/cm<sup>2</sup> (19,000 pounds/in.<sup>2</sup>); the well produced 1.1 million m<sup>3</sup> (40 million ft<sup>3</sup>) of emissions/day. The emissions were ignited because the gas was composed of 35% H<sub>2</sub>S. A herd of red and gray Brahman was examined 5 days after the blowout started. Clinical findings were irritation of the eyes and respiratory tract. Of the 55 animals with signs of respiratory distress 25–30 days after the blowout started, 15 remained clinically affected approximately 9 months later.

A sour gas well blowout occurred in western Canada in 1984, and unrestricted emission of sour gas occurred

TABLE 61.7 Chemical composition of the Drummond 6-30 well

Compound	Concentration (ppm)
Hydrogen sulfide	11,400
Methyl mercaptan (methanethiol)	57.0
Carbonyl sulfide	22.0
Ethyl mercaptan (ethanethiol)	14.7
Propyl mercaptan	14.3
Carbon disulfide	4.8
Butyl mercaptan	3.3
Dimethyl disulfide	<0.5

for 88 h (Anonymous, 1986). Flow rates for the well were estimated at 239,000 m<sup>3</sup>/day. The approximate concentration of sulfur-containing compounds is given in Table 61.7. A total of 195 measurements of H<sub>2</sub>S were made with mobile monitors in the blowout area; the concentrations ranged from 0.014 mg of H<sub>2</sub>S/m<sup>3</sup> of air to 4.90 mg of H<sub>2</sub>S/m<sup>3</sup>. Monitoring of H<sub>2</sub>S did not occur until 5 h after the blowout. The blowout occurred on September 25, 1984. A team of veterinarians conducted an investigation into possible effects of the well emissions on livestock health. Sixteen ranches were visited, and 5 ranches received detailed investigations. General complaints consisted of irritation of ocular and respiratory membranes, respiratory disease (pneumonia), reduced exercise tolerance, and reproductive failure. A ranch located approximately 2 km from the well had 151 head on a fattening ration. These animals were exposed to unknown levels of sour gas in the first few hours after the blowout. Subsequently, mobile monitors recorded 1.0–50 ppm H<sub>2</sub>S in the vicinity of the cattle. Mobile monitoring with handheld monitors was done primarily for access to the area under emergency management controls. Subsequent to the exposure to sour gas, the majority of the 151 head of fattening steers showed irritation of ocular and nasal membranes and had abnormal lung sounds and exertional dyspnea. The signs suggested an impending outbreak of infectious respiratory disease. However, these signs abated without treatment over a period of several weeks. One animal was necropsied and found to have necrobacillosis. Another animal had CNS signs that responded to thiamine; thus, a putative diagnosis of thiamine-responsive polyoencephalomalacia was made. There is a relationship between dietary sulfur and the occurrence of thiamine-responsive polyoencephalomalacia (Gould, 2000). The team concluded that reasonable evidence existed that the emissions may have produced a transient respiratory disease in feeder cattle (chemical pneumonia) and reduced the feeding performance of these animals and extended the time necessary to carry them on feed. The rancher was evacuated from the farm soon after the blowout, and the feeding regimen was disrupted for 3 or 4 days. The owner of a ranch located 2 km east of the well site reported reproductive

failure, loss of weight and condition, and loss of stamina in horses. The team concluded there was no evidence that the reproductive failure in these mares or the loss of weight and condition were related to emissions from the well. However, it is possible that emissions from the well may have had a transient effect on exercise tolerance in these animals. A similar complaint of reduced exercise tolerance was reported from a second farm approximately 3 km northeast of the well site. In this case, an infectious disease was likely occurring concurrent with exposure to the emissions and was probably the cause of reduced exercise tolerance in these horses. Exposure to well emissions may have had a transient contributory effect. A few of the other farms in the surrounding area also reported a transient ocular and nasal irritation in the animals but did not report any reduction in exercise tolerance, condition, or reproductive performance. The investigation team concluded that in several farms up to a 4-km radius from the well site, emissions from the well probably caused transient ocular and respiratory irritation in livestock, primarily horses and cattle. Irritation of sensitive membranes may also have occurred in livestock more distant from the well site, but it was probably not a significant factor. On a farm approximately 8 km from the well site, an outbreak of infectious respiratory disease (pneumonia) and keratoconjunctivitis (pink-eye) occurred. It was not possible to relate these events directly to emissions from the well. However, it is possible that emissions may have played a minor role in increasing the severity of the disease.

Mostrom (1995) and Mostrom and Campbell (1996) investigated the effects of a leak from a sour multiphase pipeline in two herds of cattle. Other investigators have provided epidemiological findings of this event (Waldner *et al.*, 1998). The sour condensate was from a sour gas field, and the sour gas contained approximately 34% H<sub>2</sub>S. The leak was discovered in January, and it is not known for how long the corroded line under a riverbed had been leaking. The condensate primarily contained C<sub>1</sub> to C<sub>9</sub> aliphatics and mono-aromatics (benzene ring). One of the herds was located immediately adjacent to a river where the pipeline break occurred, and it was later moved to a farm approximately 4.5 km from the site. The other herd was located approximately 4 km from the site. The herds were exposed to emissions from the pipeline and also to emissions from the cleanup operations. Burning fugitive sour condensate and washing river gravel were the methods used to remove crude petroleum from river ice, the river bottom, and riparian lands. Emissions from the cleanup operations were freely released into the atmosphere. Cow and calf mortalities occurred. This investigation found clinical evidence of exposure to an irritating substance and evidence of endocrine disruption and immune and nervous system dysfunction. Infections with organisms

considered opportunists (*Enterococcus fecalis* and *Corynebacterium xerosis*) were observed in calves. Some cows developed aggressive behavior, and some had apparent proprioceptive dysfunction. Pregnant cows were observed *in estrus*, and they did not have physiologic signs of prepartum. Many of the calves lacked the suckling instinct, and some cows failed to nurture newborn calves. More than 1400 tissue specimens were collected. Stair *et al.* (1996) reported on the histopathological findings in these herds. Histopathology observed included tracheal hyperplasia of the submucosal glands, discharge of the goblet cells and squamous metaplasia, thyroid and lymphoid hypoplasia, cytoplasmic vacuolization of the gasserian ganglion, and a rare cerebellar neuroblastoma. The epidemiologic study reported that cattle were managed to mitigate exposure to pollution from the sour gas leak (Waldner *et al.*, 1998). Calf mortality increased with cold weather at the time of birthing and with the occurrences of twinning. An association between calf mortality and distance from the pipeline corrosion-induced leak site and wind direction in the Red Deer River Valley was not found. Managing cattle to mitigate exposure to pollution was considered a factor in increasing calf mortality. It is important to note that cold temperatures ( $-16^{\circ}\text{C}$ ) have been reported to cause  $\text{SO}_2$  to induce an increase in metabolism and an increase in nutrient requirements of cattle (Komarnisky, 2003).

## HYDROGEN SULFIDE

Hydrogen sulfide is a constituent of sour gas and other crude petroleum. In sour gas,  $\text{H}_2\text{S}$  can be present at a concentration of less than 1% to greater than 90% (Reiffenstein *et al.*, 1992). Incident-related exposures to  $\text{H}_2\text{S}$  are generally exposures to complex chemical mixtures. The lethality of  $\text{H}_2\text{S}$  is similar across species (Reiffenstein *et al.*, 1992). Studies have shown that wells and associated activities are important sources of  $\text{H}_2\text{S}$  (Burstyn *et al.*, 2007). Hydrogen sulfide is used in relative pure form for heavy water production. It is produced by anaerobic digestion and is present in manure and sewer gas, and it has an offensive odor of rotten eggs. Hydrogen sulfide disassociates in water ( $\text{H}_2\text{S} \leftrightarrow \text{HS}^- + \text{H}^+ \leftrightarrow \text{S}^{2-} + 2\text{H}$ ) to give the hydrosulfide anion ( $\text{HS}^-$ ) and the sulfide anion ( $\text{S}^{2-}$ ), and disassociation is affected by pH and buffering capacity of the solution. At pH 7.4 (physiological pH), approximately 33% exists in the undisassociated form and the rest as the hydrosulfide ion ( $\text{HS}^-$ ). Hydrogen sulfide is also lipid soluble and is soluble in cell membranes. These properties are considered important in the toxicity of  $\text{H}_2\text{S}$ .

## Gasotransmitter

Hydrogen sulfide has been identified as an endogenous gasotransmitter. It is produced endogenously in tissues by cystathionine  $\beta$ -synthase, cystathionine  $\gamma$ -lyase, and/or mercaptopyruvate sulfurtransferase (Gadalla and Snyder, 2010; Liu *et al.*, 2011). These enzymes produce  $\text{H}_2\text{S}$  in micromolar to picomolar concentrations, and this range is considered to be the physiologic levels. As a gasotransmitter,  $\text{H}_2\text{S}$  is vasoregulatory and appears to act in cell signaling in inflammation and in nervous system modulation. Hydrogen sulfide is a modulator of potassium, calcium, and chloride ion channels (Tang *et al.*, 2010). Phase I studies on  $\text{H}_2\text{S}$  in rats have shown that it has potential as a drug in preventing cellular damage associated with ischemic-reperfusion injury (Henderson *et al.*, 2011). This likely has links with modulation of ion channels.

## Effects on metabolism and the endocrine system

Mice exposed to 80ppm  $\text{H}_2\text{S}$  for 5min had an approximately 50% drop in oxygen consumption and an approximately 60% reduction in carbon dioxide output (Blackstone *et al.*, 2005). During 6h of exposure, the metabolic rate dropped by approximately 90% and core body temperature dropped to approximately  $2^{\circ}\text{C}$  above ambient temperature, and oxygen uptake and carbon dioxide output were approximately 10% of pre-exposure value. There was a linear relationship between core body temperature and  $\text{H}_2\text{S}$  concentration. No adverse neurological effects were observed. Mice exposed to 150ppm  $\text{H}_2\text{S}$  for 20min survived exposure to 5% oxygen for 1h and then 3% oxygen for 3.5h without apparent detrimental effects (Blackstone and Roth, 2007). A study in piglets showed that 80ppm  $\text{H}_2\text{S}$  increased metabolism and was a hemodynamic stimulant (Li *et al.*, 2008). Similar observations have been made in 24-kg pigs (Drabek *et al.*, 2011). Brain weights from male rats and mice exposed to 80ppm  $\text{H}_2\text{S}$  were significantly reduced (Dorman *et al.*, 2004). There appears to be both a strain and a sex variation in the sensitivity of rats to  $\text{H}_2\text{S}$ . It is of interest that there are no reports of hypoactivity in mice in these studies (Dorman *et al.*, 2004).

## Reproductive toxicology

Studies have shown that development effects of  $\text{H}_2\text{S}$  can occur. Rats were exposed to 20 or 75ppm  $\text{H}_2\text{S}$  7h/day from gestation day 5 to postpartum day 21, and control groups were included for each exposure level (Skrajny *et al.*, 1992). Serotonin and norepinephrine

levels were assayed in the developing rat cerebellum and frontal cortex. In rats exposed to 75 ppm H<sub>2</sub>S, serotonin levels were increased on days 14 and 21 postnatal in the cerebellum and frontal cortex, and norepinephrine levels were significantly increased on days 7, 14, and 21 postnatal in the cerebellum and on day 21 in the frontal cortex. Exposure to 20 ppm H<sub>2</sub>S significantly increased the levels of serotonin in the frontal cortex on day 21 postnatal, and the levels of norepinephrine were significantly reduced in the frontal cortex on days 14 and 21 and on day 14 in the cerebellum. Exposures to H<sub>2</sub>S at 20 and 50 ppm for 7 h/day from day 5 postcoitus to day 21 postnatal were shown to alter developing cerebellar Purkinje cell dendritic branching (Hannah and Roth, 1991; Roth *et al.*, 1995). In a fertility and developmental study, rats were exposed to 0, 10, 30, or 80 ppm H<sub>2</sub>S 6 h/day, 7 days/week for 2 weeks prior to breeding, during a 2-week mating period (Dorman *et al.*, 2000). Exposures continued from gestation day 0 through gestation day 19. Exposure of dams and pups resumed between postnatal days 5 and 18. No changes in the fertility indices were reported. Male F<sub>0</sub> rats in the 80-ppm group had testicular tubular degeneration, and dose-response linkages to H<sub>2</sub>S exposure were not established. A litter of pups in the 30-ppm exposure group developed epidermolysis bullosa-like lesions. The authors considered this to be the first report of this lesion in the rat, and its linkage to H<sub>2</sub>S exposure is unknown. No other teratologic lesions that can possibly be related to H<sub>2</sub>S exposure were reported. No pathophysiologic neuropathies were reported. The cerebellum was not evaluated by histopathology for arrangement of the Purkinje cell dendrite fields. Sulfide could be an endocrine disruptor by blocking or reducing the number of oxytocin receptors in rat uterus and may modulate uterine contractions (Hayden *et al.*, 1989; Hu *et al.*, 2011). Hydrogen sulfide is also implicated in insulin regulation and in regulation of the hypothalamic-pituitary axis.

## Biochemical toxicology

Hydrogen sulfide disrupts biochemical processes. The biochemical effects of H<sub>2</sub>S have been investigated (Reiffenstein *et al.*, 1992; Khan *et al.*, 1990, 1998). Exposure of rats to H<sub>2</sub>S at 100 ppm for 8 h/day, 5 days/week for 5 weeks reduced the activity of erythrocyte superoxide dismutase (SODe), exposure at 10 and 100 ppm reduced the activity of pulmonary cytochrome *c* oxidase, and there was a trend for brain cytochrome oxidase to be decreased. Rats exposed to various concentrations of H<sub>2</sub>S showed that 10 ppm did not suppress the activities of cytochrome *c* oxidase in lung tissue. Exposure to greater than 500 ppm caused greater than 90% suppression of cytochrome *c*

oxidase and succinate oxidase activity in lung tissue. At 200 and 440 ppm H<sub>2</sub>S exposure levels, pulmonary cytochrome *c* oxidase activity increased at 24 and 48 h postexposure. NADH-cytochrome *c* reductase and succinate reductase were not inhibited by H<sub>2</sub>S *in vivo* and by exposure to sulfide *in vitro*. In H<sub>2</sub>S exposures, mitochondrial swelling is an early histopathologic observation that occurs before cellular necrosis. The *in vitro* effects of sulfide, sulfite, and sulfate on the activities of SODe, catalase, glutathione peroxidase (GSHPX), and glucose-6-phosphate dehydrogenase (G6PDH) were studied in hemolyzates of bovine erythrocytes (Khan *et al.*, 1987). A concentration-dependent inhibition in the activities of these enzymes was observed, but their effects on each enzyme were different. The study showed that SODe and catalase activities were most sensitive to sulfide, followed by sulfite and sulfate. The GSHPX activity was most sensitive to sulfite, followed by sulfide, cysteine, and sulfate. The activity of G6PDH was maximally inhibited by reduced GSH, followed by sulfite, and sulfate and sulfide were inhibitory only at high concentrations. Dialysis of the sulfide- and sulfite-inhibited enzymes resulted in complete or partial reversal of inhibitory effects. These enzymes are important in scavenging free radicals.

## Pathology of hydrogen sulfide

Detailed reports on the experimental pathology of H<sub>2</sub>S and sour gas in cattle do not appear to exist in the scientific literature. Concentration and duration of exposure are important with regard to the toxicological effects of H<sub>2</sub>S (Prior *et al.*, 1988). There are reports on the toxicopathology of H<sub>2</sub>S in other species. Ocular lesions in rats included corneal edema and necrosis, and detachment of corneal epithelial cells has been reported for experimental H<sub>2</sub>S exposures of 56 mg/m<sup>3</sup> (Beasley, 1963; Lopez *et al.*, 1989). Calves continually exposed to H<sub>2</sub>S by inhalation developed corneal opacity (Nordstrom, 1975; Beauchamp *et al.*, 1984). Unfortunately, the corneal pathology was not described in these reports.

Hydrogen sulfide is toxic to the respiratory tract, and the toxic effect may be mediated through inhibition of cytochrome *c* oxidase. Exposure of rats to 560 mg H<sub>2</sub>S/m<sup>3</sup> for 4 h caused exfoliation of respiratory epithelia and olfactory cells, with the exfoliation of the olfactory cells continuing for more than 44 h (Lopez *et al.*, 1988). Lopez *et al.* (1987) also reported that exposure of rats to H<sub>2</sub>S concentrations of 0, 10, 200, and 400 ppm for 4 h increased the cellularity of nasal saline washes by 0, 139, 483, and 817%, respectively. Lopez *et al.* (1988) exposed rats to 0, 14, 280, or 560 mg of H<sub>2</sub>S/m<sup>3</sup>, respectively. Squamous epithelium appears to be resistant to the corrosive effects of H<sub>2</sub>S, and lesions were not observed in these regions of the nasal epithelium.

Lesions of the respiratory and olfactory epithelium were observed in all of the rats exposed to 560 mg H<sub>2</sub>S/m<sup>3</sup>. Cellular necrosis, erosions, and ulcers of the respiratory epithelium were observed. Twenty hours after exposure, eroded or ulcerated areas were covered by a thin layer of basophilic cells, and a neutrophilic exudate was observed in the lamina propria and submucosa. At 44 h after exposure, the respiratory epithelium was covered with pre-ciliated secretory cells, and mitotic figures were observed. Specific lesions were observed in the olfactory epithelium. There were multifocal areas of cellular necrosis, and the lesions were more pronounced at 20 h after exposure. Evidence of healing was not observed 44 h after exposure. Rats exposed to 2317.6 mg of H<sub>2</sub>S/m<sup>3</sup> or rats given intraperitoneal injections of sodium bisulfide died within 3 min (Lopez *et al.*, 1989). The rats that were exposed to H<sub>2</sub>S had massive extravasation of eosinophilic fluid into the bronchoalveolar space. Mature rats and mice were exposed (whole body) to 0, 10, 30, or 80 ppm H<sub>2</sub>S for 6 h/day for at least 90 days (Dorman *et al.*, 2004). Pathology was observed in mice exposed to 80 ppm H<sub>2</sub>S. Infiltration of the nasal epithelium or lamina propria by inflammatory cells, predominantly neutrophils, was observed. The infiltrate was often accompanied by serocellular exudate, epithelial hyperplasia or hypertrophy, squamous metaplasia, erosion or ulceration, cystic epithelial invaginations, fibrosis, hyperkeratosis, or goblet cell hyperplasia. Neuronal loss was observed in the olfactory epithelium of rats and mice exposed to 30 ppm H<sub>2</sub>S. A strain and sex difference appears to exist in rats. Ciliated cells in the nasal passages, trachea, and bronchi are sensitive targets for airborne irritants, including H<sub>2</sub>S, SO<sub>2</sub>, and NO<sub>2</sub>. The ciliated cells are part of the mucociliary escalator that transports mucus and foreign particulate matter from the lower respiratory tract toward the pharynx, where it is swallowed, and from the nasal passages to exit at the nares. The cilia of the columnar epithelium are lost following exposure to irritating airborne substances. Loss of cilia or ciliated cells can alter the defense mechanism of the respiratory tract against particulate substances. The olfactory epithelium is considered a sensitive target in the nasal passages for H<sub>2</sub>S. Lesions of the olfactory epithelium could modify maternal behavior by altering offspring recognition.

Massive pulmonary edema was the pathological finding in humans killed by accidental exposure to H<sub>2</sub>S and in rats experimentally exposed to high concentrations of H<sub>2</sub>S (Burnett *et al.*, 1977; Lopez *et al.*, 1986, 1987, 1988, 1989). Rats exposed to approximately 2317 mg H<sub>2</sub>S/m<sup>3</sup> died within 3 min from pulmonary edema (Lopez *et al.*, 1989). The edema fluid was highly eosinophilic and located in perivascular space and the alveoli. Lethal injections of sodium hydrosulfide did not produce pulmonary lesions. Lopez *et al.* (1986) exposed rats to 0, 56,

and 420 mg of H<sub>2</sub>S/m<sup>3</sup> for 6 h. Mild pulmonary edema was observed in rats immediately after exposure to 56 mg H<sub>2</sub>S/m<sup>3</sup> and in rats that were killed by exposure to 420 mg H<sub>2</sub>S/m<sup>3</sup>. Pulmonary edema was described as primarily perivascular, and edema fluid was rarely observed in the alveoli. Pulmonary edema was not observed in rats exposed to 56 mg/m<sup>3</sup> at 18 and 42 h after exposure. Lymphocytic disruption of the lymph nodes and thymus appeared to increase in severity and frequency in the high-dose group. Because nasal ulcers were observed in all of the rats, activation of the immune system could increase the sensitivity of lymphoid tissue to H<sub>2</sub>S. The cells present in the nasal washes were exfoliated epithelial cells and neutrophils. A 3000% increase in the protein concentrations in bronchoalveolar lavage fluids was observed 1 h postexposure in rats exposed to 400 ppm H<sub>2</sub>S. The increase in protein and leukocytes was considered to be the result of alterations of vascular permeability induced by H<sub>2</sub>S. Dorman *et al.* (2004) observed that exposure of rats and mice to 30 or 80 ppm H<sub>2</sub>S caused bronchiolar epithelial hypertrophy and hyperplasia. The epithelial changes were variably associated with peribronchiolar fibrosis and smooth muscle hypertrophy and often mixed inflammation. Brain weights from the male Sprague–Dawley rats and the male B6C3F1 mice in the 80-ppm exposure group were significantly reduced (Dorman *et al.*, 2004).

### Experimental studies: cattle

Nordstrom (1975) exposed calves to ammonia (NH<sub>3</sub>) and H<sub>2</sub>S gases individually or in combinations. Calves were housed and exposed in uniquely designed exposure chambers. A manure pack was established in each chamber to stabilize a background production of NH<sub>3</sub> at approximately 12.95 ± 5 ppm. Hydrogen sulfide was not identified in the manure gas. Calves were placed in the chambers for a 7-day acclimation period and were exposed to the background level of NH<sub>3</sub> during this interval. The acclimation interval was immediately followed by 7-day exposure to H<sub>2</sub>S. A 7-day observation period completed the experiment. The predominant clinical sign in all treatment groups was ocular irritation as indicated by erythema and excessive lacrimation. Ocular irritation was observed at the background levels of NH<sub>3</sub>. Nasal irritation, based on serous discharge from the nose, was observed at 65 ppm of NH<sub>3</sub>, and the serous discharge was profuse at 150 ppm NH<sub>3</sub>. Dry coughing was also observed, especially at 150 ppm NH<sub>3</sub>. At 150-ppm exposure, the calves kept their eyes closed and had irregular shallow breathing. Based on diminishing clinical signs during the exposure periods, the author concluded that the calves appeared to develop some adaptation to NH<sub>3</sub>. The calves were distressed and

depressed by all exposure levels of  $\text{H}_2\text{S}$ . Signs of distress were restlessness, pawing, head shaking, tail switching, blowing through the nose, licking of the nose, and slobbering with the tongue protruding. Signs of depression were heads lowered and eyes closed. Diarrhea and vomiting were observed in some calves. Breath-holding, panting, dyspnea, shallow breathing, and spasmodic coughing were signs of respiratory distress. Epistaxis was also observed. Neurological effects (nystagmus and depression) were reported. Ocular irritation appeared to be profound, and at 150 ppm  $\text{H}_2\text{S}$  exposure, the effect was described as degenerative. Photophobia and refusal to open the eyelids were observed at the 20-ppm level of exposure. At the high-exposure level, corneal opacity was severe, and the animals were diagnosed as blind. Keratoconjunctivitis and vesicular keratitis were observed. At the end of the exposure interval, rupture of the cornea seemed imminent. The eyes of white-faced calves appeared to be more susceptible to the irritating and inflammatory effects of  $\text{H}_2\text{S}$  than those of calves with pigmented skin around the eyes. Clinical signs of the effects on the upper respiratory tract were more severe in calves exposed to  $\text{NH}_3$  plus  $\text{H}_2\text{S}$ . The severity of epistaxis increased at the exposures to high levels of  $\text{H}_2\text{S}$  plus  $\text{NH}_3$ , and the author considered the effects to be additive or synergistic. The combination of 150 ppm  $\text{H}_2\text{S}$  plus 150 ppm  $\text{NH}_3$  decreased respiration from a pre-exposure rate of 87/min to 63/min. Based on clinical evaluations of the ocular lesions at the 150-ppm  $\text{H}_2\text{S}$  level of exposure, the author concluded that  $\text{NH}_3$  at 150 ppm decreased the effects of exposure to 150 ppm  $\text{H}_2\text{S}$ . Rumen motility was considered decreased in both rate and intensity. Exposure to  $\text{H}_2\text{S}$  plus background  $\text{NH}_3$  decreased feed consumption by 3.5 and 26% for 20- and 150-ppm levels of exposure, respectively. Animals exposed to 20 ppm  $\text{H}_2\text{S}$  tended to recover appetite during the latter part of the exposure interval. During the 7-day postexposure interval, feed consumption increased and was higher than that for the background  $\text{NH}_3$  values. At levels of 20 ppm  $\text{H}_2\text{S}$  plus 65 ppm  $\text{NH}_3$ , appetite depression in the calves was more or less comparable to that of calves exposed to 20 ppm  $\text{H}_2\text{S}$  plus background  $\text{NH}_3$ . Feed consumption in calves exposed to 20 ppm  $\text{H}_2\text{S}$  plus 150 ppm  $\text{NH}_3$  was decreased 6.5%, or essentially double the appetite depression observed in calves exposed to 20 ppm  $\text{H}_2\text{S}$  plus background  $\text{NH}_3$ . Exposure to 150 ppm  $\text{H}_2\text{S}$  plus 150 ppm  $\text{NH}_3$  caused a 32.5% decrease in feed consumption compared to that of the calves exposed to 20 ppm  $\text{H}_2\text{S}$  plus background  $\text{NH}_3$ . These observations suggest that the ratio of  $\text{H}_2\text{S}$  to  $\text{NH}_3$  in the exposure mixture alters the interactive effect. Clinicopathology observations were reported. Sulfhemoglobin was not detected in the blood from calves exposed to 20 ppm  $\text{H}_2\text{S}$ . Statistically significant changes were not observed in levels of blood ammonia, urea nitrogen and uric acid, serum

concentration of bilirubin, glucose, phosphorus, calcium, total protein, albumin and cholesterol, or the activities of the enzymes glutamic oxalacetic transaminase, lactic acid dehydrogenase, and alkaline phosphatase. Leukocytosis was observed in two calves exposed to  $\text{H}_2\text{S}$  plus background concentrations of  $\text{NH}_3$ .

Goats were essentially continuously exposed to  $\text{H}_2\text{S}$  during a 96-h interval in an exposure hood delivery system (Hayes, 1972). The exposure hood controlled the ambient environment around the head and neck of the animals but permitted the animals to eat and drink. Exposure concentrations of  $\text{H}_2\text{S}$  were as follows: 0.0 ppm, four goats; 10 ppm ( $13.9 \text{ mg/m}^3$ ), four goats; 50 ppm, four goats; and 100 ppm, five goats. Goats exposed to 50 or 100 ppm  $\text{H}_2\text{S}$  trembled during activity. A decrease in urinary volume corresponded to a decrease in water consumption. At 50 ppm of exposure, epiphora occurred 24 h after exposure and persisted for the remainder of the exposure interval. Epiphora also occurred with exposure to 100 ppm  $\text{H}_2\text{S}$ , and ocular injury was visible following 24–48 h of exposure. Corneal opacities, which were considered to be reversible, caused partial loss of vision. There was a trend for exposure to  $\text{H}_2\text{S}$  to decrease intake of feed. In animals exposed to 10 ppm, there was a trend to recovery during the exposure period, and the overall decrease in feed consumption was 20%. Exposure to 50 ppm  $\text{H}_2\text{S}$  decreased feed and water intake, especially on the first day of exposure. Although a trend to recovery was observed, complete recovery did not occur. For the 50- and 100-ppm exposure groups, feed consumption decreased on exposure day 2 (37% decrease for the 100-ppm group) and remained depressed through exposure day 4. For the 10-ppm group, there was a decrease in water consumption on exposure day 1 and a rebound on days 2–4. For the 50-ppm group, there was a sharp decrease in water consumption on exposure day 2. For the 100-ppm group, water consumption was also decreased. The author concluded that there was a dramatic decrease in the desire of the goats to consume food and water. Plasma levels of cortisol were increased 48 and 55% in the 50- and 100-ppm groups, respectively. Respiratory and heart rates and blood pressure were recorded each day at 08:00, 10:00, 13:00, and 16:00 h. These data suggest that initial exposure to  $\text{H}_2\text{S}$  at the 10- and 20-ppm levels caused a decrease in respiratory rate on day 1 of exposure. The 0.0- and 10-ppm treatment groups were not different with regard to respiratory rate; exposure to 50 ppm significantly decreased respiration from 19.8 respirations/min on exposure day 2 to 16.5 respirations/min on day 3; goats exposed to 100 ppm had a significant decrease in respiratory rate on the last 2 days of exposure. Exposure to  $\text{H}_2\text{S}$  did not significantly alter heart rate, blood pressure, or rectal temperature; however, there was a trend for rectal temperature to increase during the exposure period.

## EXPOSURE TO ENVIRONMENTAL SULFUR

The impact of elemental sulfur on cattle, especially to producers in close proximity to sulfur stockpiles, is a concern to cattle producers. A study was done on the impact to cattle of fugitive sulfur and other pollution from sulfur mines in Poland (Janowski and Chmielowiec, 1981). The principal pollutants were sulfur dust, sulfur gases, SO<sub>2</sub>, and sulfur hydride. Fifty-five cattle within 1 km of the mine were evaluated during the summer months on pasture and during the winter months when the cattle were predominantly stabled. The control group of 27 cattle was kept in an area that was free of sulfur pollution, 20 km from the mine. Analyses for sulfur dust and sulfur compounds are summarized in Table 61.8. Clinical findings in the polluted area were (1) decreased occurrences of infestation with external parasites and mycotic skin infections (ringworm); (2) increased body temperature and heart and respiratory rates; and (3) decreased nociceptive response. Other findings were abnormal eyes (90.4%), respiratory disease (94.2%), and digestive disorders (21.1%). Clinical findings in the eye were epiphora, erythema of the conjunctiva, and edema of the eyelids. Abnormal findings of the respiratory system included dyspnea, coughing, mucopurulent nasal discharge, and abnormal pulmonary sounds. Digestive disorders included abnormal ruminal motility and diarrhea. Cattle were healthier when kept indoors. Cattle in areas polluted with sulfur, compared to controls, had a decreased burden of parasites in the digestive tract. Pathological findings in the sulfur-exposed cattle were as follows: the respiratory tract contained gray-yellow tinged mucus; inflammation of the trachea; thinning of cellular layers in the bronchi, almost to the point of squamous metaplasia; and interstitial inflammation. The authors concluded that sulfur pollution produces intoxication in the form of a chronic disease that they called sulfurosis.

## TOXICOLOGY OF SULFUR DIOXIDE IN CATTLE

Sulfur dioxide emissions are an important issue with regard to oil and gas pollution because a single sour gas plant removing sulfur from sour gas and operating at efficiencies approaching 100% can have stack emissions of approximately 10 metric tons of SO<sub>2</sub> per day (Waldner, 2001). A relatively small area with several sour gas plants can have emissions of 67–85 tons of SO<sub>2</sub>/day. Inhalation studies (head-only exposure) in cattle showed that SO<sub>2</sub>

TABLE 61.8 Concentrations of sulfur and sulfur compounds in sulfurosis study

Parameter	Study areas	Control areas
Urinary sulfur	Barn, 3.01 g/L Outdoors, 5.33 g/L	0.52 g/L
Milk sulfur	1.87 g/L	0.30 g/L
Serum sulfur	2.58 g/L	0.46 g/L
Sulfur dust	Barn, 1.02 g/m <sup>2</sup> Outdoors, 1.31 g/m <sup>2</sup>	ND
Sulfur dioxide	Barn, 0.089 mg/m <sup>3</sup> (0.034 ppm)	ND
Hydrogen sulfide	Barn, 0.178 mg/m <sup>3</sup> (0.128 ppm) Outdoors, 0.089 mg/m <sup>3</sup> (0.064 ppm)	Barn, ND Outdoors, 0.002 mg/m <sup>3</sup>

ND, not detectable.

had an effect on the immune system and on metabolism, and cold temperature had an effect on SO<sub>2</sub> toxicity (Komarnisky, 2003). A brief summary of this study is given. Eight steers were progressively exposed to room air containing 1 ppm SO<sub>2</sub> for 10 days, 5 ppm SO<sub>2</sub> for 7 days, and 20 ppm for 7 days. Four steers were exposed to SO<sub>2</sub> at room temperature (~18.5°C), and four steers were exposed to SO<sub>2</sub> at -16°C. In the cold environment, the metabolic rate was increased by 33, 39, and 44% at 1, 5, and 20 ppm of SO<sub>2</sub>, respectively. Exposure to SO<sub>2</sub> in the warm environment did not significantly alter metabolic rate. For a 500-kg steer intermittently exposed to 1 ppm of SO<sub>2</sub>, the extra feed required for maintenance and growth would be equivalent to an additional 1.5 kg/day of grain or 2.1 kg/day of hay. Sulfur dioxide was shown to have immunotoxic effects in cattle. Exposure of steers to 5 and 20 ppm in the cold environment decreased the respiratory bursts in neutrophils. Exposure to SO<sub>2</sub> in the cold environment decreased the threshold dose for shedding of respiratory epithelial cells into bronchoalveolar lavage (BAL) fluid. Neutrophil numbers in BAL were increased by exposure to SO<sub>2</sub>, and exposure to cold temperature further increased neutrophil numbers. Exposure to SO<sub>2</sub> decreased the number of pulmonary macrophages in BAL fluid. At the 20-ppm level, lactate dehydrogenase was increased in the BAL fluid.

## PATHOLOGY OF PETROLEUM AND OIL FIELD CHEMICALS

### Clinical pathology

Barber *et al.* (1987) reported on the toxicology of aviation turbine fuel in heifers. Ten animals were considered to

have elevated serum activity of aspartate aminotransferase, interpreted as a reflection of acute hepatic dysfunction, and the activity of  $\gamma$ -glutamyl transpeptidase (GGT) was considered to be within the normal range. Elevated concentrations of nonesterified fatty acids were observed in 11 of the animals, 2 had elevated concentrations of blood urea nitrogen, and 5 had a leukocytosis. Six weeks after the initial farm visit, 41 of 41 animals had elevated serum activity of GGT.

Bystrom (1989) found that sweet crude oil did not alter hematological parameters. There was a correlation between the severity of clinical signs and increased concentrations of plasma fibrinogen. The activity of hepatocellular enzymes in serum and serum glucose was not consistently increased after exposure to sweet crude oil, but serum calcium and potassium values consistently decreased and bilirubin values consistently increased. Rowe (1972) found that hematological parameters, especially leukocyte numbers, were elevated as chemical pneumonia advanced. A single dose of sour crude oil caused a constant decline in plasma glucose. A transient decline in plasma glucose was observed in calves given sweet crude oil or kerosene. Exposure to grease has been reported to cause changes in hematology and clinic chemical parameters (Wallace and Blodgett, 1996). A cow exposed to lithium grease had leukopenia ( $3.7 \times 10^9$  white blood cells/L), lymphopenia ( $1.8 \times 10^9$  lymphocytes/L), and hyperfibrinogenemia (6 g/L, with the normal given as  $<5$  g/L). Triaryl phosphates (TAP) have greater affinity for pseudocholinesterase, also known as plasma cholinesterase or butyrylcholinesterase, than for acetylcholinesterase (Abou-Donia and Gupta, 1994). Erythrocytic acetylcholinesterase was inhibited for a short duration after a calf was initially dosed with 10 g of TAP/kg BW, and the dose was repeated as 5 g/kg BW on day 30 and as 10 g/kg BW on day 56 (Dollahite and Pierce, 1969). In four animals poisoned with tri-*o*-tolyl phosphate, changes in the routine automated clinicochemical and hematological parameters were not observed (Nicholson, 1974). In an experimental study, three calves were given oral doses at 5, 10, or 20 g of TAP/kg BW, with the total dose divided equally over 10 days (Beck *et al.*, 1977). On day 8 or 9, there was a 70–77% reduction in the activity of whole blood acetylcholinesterase. In one calf given 5 g/kg BW as a single oral dose, activity of whole blood acetylcholinesterase was reduced by 68% on day 2 and by 78% on day 9. In cows dosed with 0.5 or 1.0 g of TAP/kg BW, activity of whole blood cholinesterase was reduced by 50 and 63%, respectively, on day 2 and by 56 and 61%, respectively, on day 7. The consensus is that a relationship between the inhibition of blood cholinesterases and organophosphate ester-induced delayed neurotoxicity does not exist (Abou-Donia and Gupta, 1994).

Exposure to nitrates from drilling fluids can cause methemoglobinemia. The concentration of nitrate and nitrite can be determined in rumen fluid, aqueous humor (anterior chamber of the eye), urine, plasma, and serum. Nitrate is reduced to nitrite, and nitrite oxidizes iron in hemoglobin to form methemoglobin.

### Pulmonary pathology of petroleum

The lung is a target for unweathered (unchanged by exposure to atmosphere) petroleum. Hydrocarbon-induced chemical (inhalation) pneumonia occurs when oil is inhaled. Aspiration of oil during emesis is the most common mechanism of inhalation exposure (Coppock *et al.*, 1986b, 1996). Necropsy findings of oil-induced chemical pneumonia have been described (Dungworth, 1985, 1993). Generally, the cranioventral lobes of the lungs are affected first. During necropsy, oil may be identified in the lungs by oil discoloration and a petroleum odor, visible oil in the lung, oil floating to the surface when a piece of lung is immersed in water or formalin, or oil layering on the surface of the supernatant when a piece of lung is homogenized. The pulmonary histopathology for unweathered petroleum is similar for the various forms of petroleum. Histopathological changes are proliferative, and macrophages with a foamy-appearing cytoplasm are found in and tend to fill the alveoli (Dungworth, 1985). In the pathogenesis, oil-containing macrophages are found in the lymphatics, especially those adjacent to blood vessels around bronchi. Fibrosis and proliferation of type II macrophages are prominent features. Foamy macrophages may be incorporated into the alveolar septa by fibroblastic proliferation. As determined by histochemistry and special stains, lipids are found in both intracellular and extracellular sites, and oil can be identified in the alveolar spaces. In the early stages, the lesion may be an acute necrotizing fibrinous bronchopneumonia. Generally, neutrophils, lymphocytes, and plasma cells surround the necrotic areas. Fibrinous exudate, inflammatory cells, and amorphous eosinophilic and oily material can fill the alveolar spaces. Plant material from aspirated ingesta may also be seen in alveoli. Fibrin hemorrhages and a mixed population of mononuclear cells may be observed on the pleural surface. Extensive coagulative necrosis and suppuration may be observed in the consolidated areas. Bacteria may be present in the necrotic areas and alveoli. Hematogenous exposure of the lungs to petroleum hydrocarbons also occurs. Volatile components of petroleum are absorbed by the gastrointestinal tract and are volatilized from the blood in the lungs. Oil emboli can occur in the lungs through absorption of oil from the gastrointestinal tract and form oil emboli that block the small blood vessels in the lungs and brain. Oil emboli

in blood vessels of the lungs and brain have not been reported in cattle intoxicated with crude petroleum. The pathogenesis and observed lesions may be altered by concurrent bacterial infection and cytotoxicity of the oil.

There are reports of pulmonary pathology for field and experimental-induced petroleum intoxication. Ulceration of the ventral aspect of the trachea can occur in kerosene poisoning, and the ulcers may be covered with a pseudomembrane (Rowe, 1972; Rowe *et al.*, 1973). Areas of the lung can be consolidated and have a dark purple, reddened, or tan-gray mottled discoloration. The areas of consolidation often have a nodular appearance. Fibrinous pleural adhesions and serofibrinous pleural exudate can occur. Pulmonary abscesses can also be observed (Rowe, 1972; Rowe *et al.*, 1973). Multiple small hemorrhages were observed in the lungs of cattle poisoned with tractor vaporizing oil (Parker and Williamson, 1951). Chemical pneumonia was reported in cattle dying from diesel fuel poisoning (Gibson and Linzell, 1948). Pneumonia and pulmonary abscesses containing gram-negative organisms were found in cattle that died acutely from drinking water contaminated with aviation turbine engine fuel (Barber *et al.*, 1987). The rumen contents smelled of oil, and the odor matched the source of the petroleum. The carcasses appeared to repel scavengers and flies, and they appeared to have retarded putrefaction. Microscopic examination of tissues from the animals that died in the first 3 weeks showed fatty degeneration of hepatocytes and focal areas of hepatitis, and one of four had tubulonephrosis, renal vascular thrombi, and interstitial nephritis. A diagnosis of pneumonia and abscesses containing gram-negative organisms was made in two of four of the animals. Approximately 124 days after the ingestion of aviation turbine fuel-contaminated water, the remaining cattle were necropsied. At slaughter, the lungs of the cattle were considered abnormal and were characterized by enlargement and gray-blue areas of varying and abnormal firmness. However, histopathological abnormalities were not observed. Infection in the lungs can occur rapidly following chemical injury. Cattle that survive for 6 weeks or longer with chemical pneumonia usually have marked loss of weight and chronic ill health (Rowe *et al.*, 1973).

Pulmonary lesions have been observed in sheep following a 1-day exposure to natural gas condensate-contaminated water (Adler *et al.*, 1992). Gross pathological observations included severe bilateral consolidations and tan to gray mottling of the ventral lobes. Histological diagnosis of the lesions was a necrotizing bronchopneumonia. There were extensive areas of coagulation necrosis bordered by a dense zone of neutrophils and lesser numbers of lymphocytes, plasmacytes, and macrophages. The alveoli were filled with fibrinous exudate and amorphous eosinophilic material.

Plant material was also observed in the pulmonary parenchyma. The pleural surface was coated with fibrin, hemorrhages, and mononuclear cells. Pathogenic and potentially pathogenic bacteria (*Mannheimia (Pasteurella) haemolytica*, *Klebsiella pneumoniae*, *Fusobacterium necrophorum*, *Actinomyces (Corynebacterium) pyogenes*, *Escherichia coli*, and *Pseudomonas* sp.) were isolated from the lungs of some of the sheep.

Experimental studies have been done with crude oil (Bystrom, 1989). Cattle were administered a sweet crude oil per gavage. Many of the animals, especially those that received larger doses of oil, had black discoloration of the lungs. Visible oil was present in the cranio-ventral lobes. In one animal, it was estimated that 80% of the lungs were affected by black discoloration, and visible oil was observed. Pathological diagnoses included pulmonary consolidation, fibronectrotizing pneumonia, pleuritis, emphysema, atelectasis, multifocal interstitial pneumonia, proliferative alveolitis, bronchopneumonia, and alveolitis. In animals that survived 8 days, hyperplasia of type II epithelial cells was observed, and the alveoli were filled with foamy, alveolar macrophages.

Lung lesions can occur when animals are exposed to gaseous petroleum and sour gas. Stair *et al.* (1996) reported lesions of hyperplasia of the submucosal glands in the trachea of cattle exposed to emissions from a multiphase sour gas leak (Mostrom and Campbell, 1996). Other lesions observed included hyperplasia of tracheal, bronchial, and bronchiolar glands; metaplasia of the tracheal mucosa; and loss of cilia from the respiratory epithelium. Lymphoid hypoplasia was also observed. A study was done in feral cats that were exposed to emissions from fires in Kuwait (Moeller *et al.*, 1994). The cats were collected in Kuwait approximately 8 months following ignition of the oil wells. To ensure that the cats had been exposed for the entire duration of the oil field fires, only cats with permanent teeth were examined. Twelve cats were collected in Kuwait City, an area that was relatively smoke-free, and 14 cats were collected in Ahmadi, a city that was partially evacuated because of intense smoke from the fires in the adjacent Bergan oil field. The findings are summarized in Table 61.9. The authors concluded that these lesions were probably reversible and were most likely caused by exposure to pollution from the oil field fires. However, other causes, such as infectious diseases and parasitism, could not be completely eliminated.

## Hepatic pathology of petroleum

Hepatic pathology can be observed following exposure to oil. Parker and Williamson (1951) reported fatty changes in the liver from a cow that had ingested tractor vaporizing oil. Fatty degenerative changes and focal

TABLE 61.9 Respiratory tract lesions observed in feral cats exposed to emissions from the Kuwait oil field fires

Lesion	Kuwait City	Ahmadi <sup>a</sup>
Mild accumulation of anthracotic pigment	5/12	11/14
Hyperplasia of bronchial and bronchiolar glands	3/12	5/14
Scattered occurrence of bronchi that were dilated and filled with cellular debris and a few neutrophils; connective tissue around bronchiolar glands contained lymphocytes and plasma cells	1/12	1/14
Hyperplasia of smooth muscle around terminal and secondary bronchioli	4/12	10/14
Tracheal gland hyperplasia and segmental thickening of the submucosa	3/12	4/14
Multifocal squamous metaplasia of tracheal mucosa	7/12	10/14
Minimal hyperplasia of the submucosal glands of the larynx, some thickening of the laryngeal submucosa, and slight goblet cell hyperplasia	2/12	0/14
Multifocal squamous metaplasia of the laryngeal epithelium	2/12	3/14

<sup>a</sup>Area of intense smoke from oil well fires.

areas of hepatitis were observed in cattle following ingestion of water contaminated with aviation turbine engine fuel (Barber *et al.*, 1987). An abnormal-appearing liver in a heifer was attributed to the ingestion of gasoline 15 months previously (Albert and Ramey, 1964). Histopathology was not provided. Pembina Cardium crude oil was found to be hepatotoxic in cattle (Bystrom, 1989). Pathological changes included swelling of the liver, increased friability, and centrilobular congestion. Cows dosed with crude oil had an increase in liver weight. Histologically, the hepatocytes contained numerous vacuoles, and these vacuoles were thought to have previously contained oil. Wallace and Blodgett (1996) reported the histopathological changes in the liver of a cow that consumed Li grease containing 2050 µg Li/g of grease. The observations were vacuolated and atrophied hepatocytes. Experimental oral exposure of cattle to lithium produced similar hepatic lesions (Johnson *et al.*, 1980). Hepatic changes observed in sheep poisoned by natural gas condensate were fatty degeneration and periportal infiltration of lymphocytes and plasma cells. Biliary hyperplasia and periportal fibrosis were also found (Adler *et al.*, 1992).

### Gastrointestinal pathology of petroleum

In oral exposure, the gastrointestinal tract has primary contact with ingested petroleum. The chemical composition of the oil will cause variation in the pathology observed. Petroleum can be observed and the odor of petroleum can be detected in the rumen and intestinal tract (Wallace and Blodgett, 1996). Kerosene-induced ulcers of the esophagus have been reported (Rowe *et al.*, 1973). Bystrom (1989) reported pyloric ulcers of the abomasum of cattle exposed to unweathered sweet crude oil. She did not report other gastrointestinal lesions. Oil-soaked ingesta can be stiff and sharp because of water repellency and puncture the gastrointestinal tract. Bumstead (1949) reported oil to be very irritating to the

intestinal tract of cattle. Ingestion of natural gas condensate was observed to produce reddening of the serosal surface of the gastrointestinal tract of sheep (Adler *et al.*, 1992). Hemorrhage into lumen of the gut was also observed. Histological observations were submucosal and mucosal congestion and mucosal and serosal hemorrhage. An inflammatory response was observed in all areas of the gastrointestinal tract. Superficial erosions, mild acute cryptitis, and neutrophilic and lymphocytic exudates were reported. Isolated necrosis of enterocytes was also observed. Lithium grease has been reported to cause gastroenteritis in cattle (Johnson *et al.*, 1980).

### Renal pathology of petroleum

The kidneys are also target organs for petroleum. Some animal species and genders within a species are more sensitive to the nephrotoxicity of petroleum than others. The sensitivity of cattle to the nephrotoxicity of petroleum has not been well defined. A cow that consumed Li grease had mild swelling and vacuolation of the proximal tubular cells (Wallace and Blodgett, 1996). Experimental oral exposure of cattle to Li grease containing 1250 µg Li/g of grease produced similar renal lesions (Johnson *et al.*, 1980). Parker and Williamson (1951) reported degeneration of the kidney in cattle after the cattle consumed tractor vaporizing oil. Tubulonephrosis, renal vascular thrombi, and interstitial nephritis were observed in cattle following environmental exposure to aviation turbine engine fuel (Barber *et al.*, 1987). Renal lesions were not observed in surviving animals slaughtered 124 days later. Renal lesions have been observed in cattle dosed with a light crude oil (Bystrom, 1989). These lesions were shrunken or collapsed glomeruli (two to five in a 4 × field), mild focal necrosis of epithelial cells in the collecting ducts, and inflammatory cells that were observed in the renal cortex. In sheep poisoned with natural gas condensate, tubular epithelial necrosis was observed (Adler *et al.*, 1992). Granular eosinophilic

casts (negative for hemoglobin) and protein droplets filled Bowman's space and many renal tubules. Inflammatory cells were seen around tubular casts.

### Nervous system pathology of petroleum

Cattle exposed orally to Li grease had slight hemorrhage into the cerebellar peduncles (Johnson *et al.*, 1980; Wallace and Blodgett, 1996). Lesions in the central nervous system were observed in sheep poisoned by natural gas condensate (Adler *et al.*, 1992). Mild perivascular hemorrhage was seen in the pia mater and in the white matter of the cerebellum and cerebrum. Increased separation between the pia and arachnoid membranes was prominent, and edema was observed in the stroma of the choroid plexus. Lesions of the central nervous system were observed in harbor seals (*Phoca vitulina*) exposed to crude petroleum (Prudhoe Bay crude oil) from the T/V *Exxon Valdez*, which grounded in Prince William Sound (Spraker *et al.*, 1994). Lesions were observed in neurons and axons of the midbrain. Histopathological observations included intramyelinic edema of the large myelinated axons, neuronal swelling, neuronal necrosis, and axonal swelling and degeneration of the midbrain. These lesions were most prominent in the thalamic nuclei. Lesions of the central nervous system were also observed in polar bears. The bears were dermally exposed to Midale crude oil (Oritsland *et al.*, 1981). The lesions consisted of degenerated and necrotic cells in the small cell pyramidal layer of the hippocampus. Other lesions observed were perineuronal vacuolation in the cerebral cortex. Enlargement of the Virchow–Robin spaces and extravasation of blood around small blood vessels occurred.

### Cardiac pathology of petroleum

Cardiac lesions associated with petroleum poisoning in cattle do not appear to have been reported, but they have been observed in sheep exposed to petroleum condensate (Adler *et al.*, 1992). Gross pathological changes included epicardial hemorrhages, serosanguineous pericardial fluid, pale-appearing myocardium, and reddened endocardium. Microscopic observations were segmental myocardial necrosis and calcification. The myofibrils had loss of cross-striations and a beaded appearance. There were multifocal areas infiltrated with lymphocytes, macrophages, and occasional neutrophils. The blood vessels were congested.

### Pathological effects of petroleum in embryos

Lesions in the bovine fetus linked to exposure to crude oil have not been reported. However, studies on the

embryotoxicity of Prudhoe Bay crude oil (PBCO) have been performed. Couillard and Leighton (1989, 1990a,b) reported that PBCO was embryotoxic and that the toxicity was different from hypoxia induced by sealing the eggs with a sealing wax. Mineral oil (USP), used as a control, was not toxic to chicken embryos. Dosages ranged from 2 to 20  $\mu$ L PBCO/egg; the oil was applied on the surface of the egg below the airspace. Hepatic lesions were hepatocellular necrosis, mineralization, and perivascular and multifocal accumulations of heterophils. Hepatocellular necrosis was dose dependent. The liver was observed to have superficial yellowish zones that were multifocal to diffuse. These yellowish zones and mineralization corresponded to areas of hepatocellular necrosis. Mineralization occurred in the necrotic areas. Vacuolation of the hepatocytes was observed. The number of mitotic figures in the liver increased with the dose. Renal lesions were limited to the mesonephros. The capillaries of the glomeruli were distended, and cellular casts and mineralization were observed in the renal tubules. Splenic lesions were limited to increased granulopoietic cells arranged in distinct cords. Other pathological findings were ascites and subcutaneous edema. Hepatic lesions were observed 2 days after treatment; renal and splenic lesions were observed on day 3. Edema fluid was more pronounced after day 3.

In another study, the toxicity of PBCO was evaluated in chicken embryos (Lusimbo and Leighton, 1996). The chicken embryos were exposed to oil on day 9 of incubation. The oil was placed on the eggshell over a prominent blood vessel of the chorioallantoic membrane. Dosages ranged from 0 to 16  $\mu$ L PBCO/egg, and embryonal mortality was dose dependent. Exposure to PBCO at 4  $\mu$ L decreased weight gain during a 3-week posthatching observation period. Lesions were observed in the liver, subcutaneous tissues, bursa of Fabricius, and pipping muscle (musculus complexus). Hepatic lesions were multifocal to locally extensive areas of hepatic necrosis and mineralization. Large fluid-filled vesicles were observed on the dorsocaudal aspect of 5 and 16% of embryos dosed with 1 and 2  $\mu$ L of PBCO, respectively. The bursa of Fabricius had depleted lymphoid tissue, and the interstitium was infiltrated with heterophils. Lesions in the pipping muscle were edema and hemorrhage, sparse multifocal fragmentation, and occasional vacuolation of the myofibers.

### Sour gas and sour condensate

Stair *et al.* (1996) reported on cattle that were exposed to sour gas/condensate from a break in a multiphase pipeline. Pathological findings in the respiratory tract included hyperplasia of the submucosal tracheal glands, discharged goblet cells, squamous metaplasia of the

tracheal mucosa, and submucosal perivascular lymphoid infiltration. Also observed was hypoplasia of the lymph nodes. These effects were associated with exposure to leaked sour gas/condensate in an area of intensive sour gas and crude oil production and processing.

### Nonpesticide organophosphorus esters

Nonpesticide phosphate esters are used as additives for lubricating oils operating under extreme conditions. Coppock *et al.* (1995a) published a review of the neurotoxicity of these esters. The pathology of TAPs has been described in several species (Craig and Barth, 1999). Specific pathological changes may not be observed during necropsy (Dollahite and Pierce, 1969; Nicholson, 1974; Beck *et al.*, 1977). Irritation and hemorrhage in the gut have been associated with TAP poisoning (Julian *et al.*, 1976). Histopathological changes of axonopathy may progress in severity toward the cell body (Maydew *et al.*, 1983; Jubb and Huxtable, 1992). The peripheral axonal lesion was described as demyelination and swelling ( $3\times$  to  $4\times$ ) of the axonal cylinders (Dollahite and Pierce, 1969). Vacuolation and degeneration of axons were observed in the sciatic and femoral nerves (Julian *et al.*, 1976). Dollahite and Pierce (1969) observed demyelination in the spinal nerve roots, of which the ventral nerve roots were the most severely affected. Cytoplasmic vacuolation of the large motor neurons was also observed. Lesions of the spinal cord were described by Nicholson (1974) as axonal degeneration in the gray matter of the ventral horn and in the ascending nerve tracts. Swelling of the axonal cylinder ( $20\times$ ), with a transition from basophilic to acidophilic staining properties, was observed in the spinal cord of cattle inadvertently or experimentally exposed to TAPs (Beck *et al.*, 1977). From lumbar to cervical regions, the lesions appeared to change in pattern and severity. Histological evidence of axonal degeneration was not observed in the L5 vertebral region; however, a few swollen axons were observed at the level of L2 and posterior thoracic (T12) vertebrae. A marked increase in degenerated axons appeared at the level of T5 and the seventh cervical vertebrae (C7). At the level of C3, the lesions were more severe at the tips of the dorsal and lateral horns. Axonal degeneration was not observed in the brain. Lesions of demyelination and degeneration were observed bilaterally in the ascending tracts of the cervical regions of the spinal cord (Julian *et al.*, 1976). The lesions were immediately ventral to the dorsolateral sulcus in the area of the spinocerebellar tract and in the fasciculus gracilis. The degenerating areas had large vacuoles containing eosinophilic globules. Prantner and Sosalla (1993) reported multifocal areas of spongiosis in the medial and lateral funiculi at the levels of vertebrae L2–L5. Focal perivascular hemorrhages

were also observed in the basal nuclei of the brain. The chemical composition of the TAP, age of the animal, and the ascending progression of lesions when they were observed may explain these discrepancies (Gupta and Abou-Donia, 1994).

### Sulfur

Pathological findings in environmental sulfur poisoning of cattle were gray-yellow tinged mucus in the respiratory tract, inflammation of the trachea, thinning of cells in the bronchus almost to the point of squamous metaplasia, and interstitial inflammation (Janowski and Chmielewicz, 1981). Sulfur dioxide produced histopathological evidence of severe irritation of the respiratory tract and eyes. Manure gas poisoning produced congestion and edema of the lungs, gastroenteritis, and peritoneal effusions.

## EPIDEMIOLOGICAL STUDIES: CATTLE

Scott and colleagues used licensed  $\text{SO}_2$  emissions from sour gas plants to estimate the exposure of cattle to emissions from oil and gas fields (Scott *et al.*, 2003a–d). Using Alberta Agriculture extension survey data for beef cattle, these authors found that there was no association for annual risk of culling, calf crop delivered, stillbirth, twinning, mortality, and calf crop weaned and exposure to  $\text{SO}_2$ . For dairy herds using Dairy Herd Improvement data, there was no association with time to culling and no association for annual culling risks and mortality. There was a small risk for increased calving interval with high exposure levels. Geographic area was interactive, suggesting the effect of emissions is subject to modification by soil type, vegetation, and climate.

A study was done in the Caroline–Sundre area of Alberta (Waldner *et al.*, 2001a,b). Seven beef herds were non-randomly selected for study, and herds with health problems previously identified with oil and gas field pollution were not included in the study. Associations were identified for exposure to unaudited industry reported oil and gas field pollution and increased calving interval, increased calf mortality, decreased cow productivity, and increased risk of stillbirth. Lead dioxide-impregnated gauze in Petri plates and filter paper impregnated with zinc acetate were used as static monitors to measure  $\text{SO}_2$  and  $\text{H}_2\text{S}$ , respectively. These static monitors were assayed every 30 days for sulfate and sulfide. Total sulfation increased the risk of odds of non-pregnancy and increased the risk of twinning. Increased  $\text{H}_2\text{S}$  increased the calving-to-calving interval and

increased the risk of nonpregnancy and abortion. The relationship between non-audited industrial reported emissions and total sulfation was not reported.

A large epidemiologic study was done on the effects of oil and gas pollution in beef cattle (WISSA, 2006; Waldner, 2008a–c). Static monitors were used to determine predominantly monthly averages of selected emissions from oil and gas field operations, including sour gas plants, gas gathering plants, and batteries (Burstyn *et al.*, 2007). Assessing exposure parameters for pollutants that are complex chemical mixtures over a wide area is difficult. The authors stated that one uncertainty in the results may be selections of split points. A substantial portion of the variability in analytical values occurred in sampling and analytical techniques. Distance from the wells rapidly decreases the concentrations of H<sub>2</sub>S, and the number of sour gas wells increases the expected concentration of H<sub>2</sub>S. Including flaring and sourness (sulfur content) of the wells improved the model fit. The primary predictor of SO<sub>2</sub> was the distance of the sampler to gas processing plants. The results suggest that SO<sub>2</sub> levels peaked during December to March. There was poor correlation between the logarithms of H<sub>2</sub>S and SO<sub>2</sub>, suggesting that SO<sub>2</sub> levels are not a good predictor for H<sub>2</sub>S levels. Sampling equipment was operating close to the lower range of sensitivity.

The positive associations with exposure to oil and gas field pollutants that have been reported are given. Calving interval in mature cows exposed to greater than 0.236 µg benzene/m<sup>3</sup> was estimated to increase by 3 days compared to that of mature cows exposed to less than 0.236 µg benzene/m<sup>3</sup> (Waldner and Stryhn, 2008). Exposure to SO<sub>2</sub> at the time of calving also increased the risk of calf mortality (Waldner, 2008d). Exposure to SO<sub>2</sub>, H<sub>2</sub>S, and volatile organic compounds measured as benzene or toluene and also SO<sub>2</sub> in the first month after calving, was associated with a minor increased likelihood of calf treatment after the first month of life. There was a linear relationship between H<sub>2</sub>S exposure and the risk of treatment. The proximity to sour gas flares was not examined. In calves that died, increasing postnatal exposures to benzene and toluene were associated with increased odds of respiratory lesions in calves older than 3 weeks (Waldner and Clark, 2009). Increasing prenatal exposure to SO<sub>2</sub> increased the odds of lesions in skeletal muscle or myocardium. The odds were higher in calves exposed to levels greater than 9 ppb SO<sub>2</sub>. Thyroid lesions of several types, including hypoplasia and lack of colloid, necrosis and degeneration, and hyperplasia, were recorded in calves aborted, stillborn, or dying postnatally. Changes were most common in stillborn calves and least in calves born alive. Calves with thyroid lesions often had other pathology as well. More work is needed to determine the importance of these findings (Waldner *et al.*, 2010).

Immune parameters in yearling cattle from 22 herds were examined for effects of ambient PM<sub>1.0</sub> and selected polyaromatic hydrocarbons (PAHs). Immune parameters were peripherally circulating B lymphocytes and CD4, CD8, γδ, and WC1 T-lymphocyte subtypes (Bechtel *et al.*, 2009a). The antibody response to rabies vaccine was also evaluated. No associations between PM<sub>1.0</sub> and selected PAHs were demonstrated in the epidemiologic models employed. In another model, in which exposures to SO<sub>2</sub>, H<sub>2</sub>S, benzene, and toluene were examined, exposure to toluene was associated with significant CD4 T lymphocytopenia (Bechtel *et al.*, 2009b). The number of CD4 T lymphocytes was 30% lower in cattle exposed to 0.823 µg/m<sup>3</sup> toluene than in cattle exposed to less than 0.406 µg/m<sup>3</sup> toluene. In a similar model, 360 newborn calves (24 h to 7 days of age) were studied (Bechtel *et al.*, 2009c). The exposure period examined was from breeding date to birth. The circulating CD4 and CD8 T lymphocyte numbers were 42 and 43% lower, respectively, in calves exposed to 0.378 µg/m<sup>3</sup> or greater of benzene compared with calves exposed to less than 0.276 µg/m<sup>3</sup> benzene. Also, CD4 T lymphocytes were 40% lower in calves exposed to 0.713 µg/m<sup>3</sup> or greater of toluene compared to calves exposed to less than 0.348 µg/m<sup>3</sup> toluene.

## WILDLIFE

The estimated production of crude oil in 2007 was approximately  $3.1 \times 10^{10}$  barrels, and approximately 50% of the oil produced was transported in international shipping lanes (Rogowska and Namiesnik, 2010). When marine spills occur, all marine animals can be at risk of intoxication and hypothermia. Birds and marine mammals are at risk of losing insulation and buoyancy after feathers or fur have been oiled. A study has shown that feathers behave as a wick, and exposure to oil has a cumulative impact on feathers (O'Hara and Morandin, 2010). It is estimated that subvisible oil sheen can reduce the insulation properties of feathers. Oil also affects metabolism in birds, and overcompensation to cold occurs (McEwan and Koelink, 1973). Birds exposed to crude oil from the "Prestige" spill were examined by pathologic methods (Balseiro *et al.*, 2005). Birds examined were predominantly common murrelets (*Uria aalge*), razorbills (*Alca torda*), and puffins (*Fratercula arctica*). Dead and live birds were classified: group 1 ( $n = 5715$ , 29%) were found dead on beaches and had varying degrees of coverage with oil, group 2 ( $n = 5172$ , 7%) comprised dead birds from the beaches that were not covered by oil, and group 3 ( $n = 51578$ , 64%) birds were recovered alive from beaches and had varying levels of oil coverage. Tissues examined by histopathology

were lung, liver, kidney, spleen, ventriculus, proventriculus, intestine, and uropygial gland. Birds in group 1 were observed to have 10–100% oil coverage and to be emaciated with severe atrophy of pectoral muscles and remarkable absence of body fat. Hemosiderin was observed in the Kupffer cells and macrophages in spleen and kidney. Urates were observed in liver, spleen, and kidney. Birds in group 2 had evidence of diarrhea, and they had hemorrhages in lungs, liver, spleen, intestine, and kidney. Birds in group 3 had previously been cleaned. They were dehydrated and had emaciation and aspergillosis of lung, air sacs, kidney, and liver. Severe dehydration and emaciation is a common finding in marine birds that have been soiled with oil. Crude petroleum in food (0.05 mL crude oil/g food/day) decreased egg production in domestic ducks (*Anas platyrhynchos*) (Harvey *et al.*, 1981). Eggshell thinning was observed. The short-day-induced decrease in serum prolactin was more pronounced in the oil-treated birds, and they were slower in restoring prolactin when exposed to long-day photoperiod. Plasma levels of corticosterone were decreased in the oil-treated birds. Plasma thyroxine ( $T_4$ ) levels were decreased in the oil-treated birds, and triiodothyronine ( $T_3$ ) levels were not changed.

In another study, south Louisiana crude petroleum in food (0.03 mL crude oil/g food/day) produced an 84% decrease in the daily rate of oviposition and increased atretic follicles (Holmes *et al.*, 1978). There was a trend for eggshell thinning. In a study in mallard ducks, dietary south Louisiana crude oil (0.03 mL crude oil/g food/day) caused a decrease in plasma estradiol during the ovulatory cycle (Cavanaugh and Holmes, 1982). In a similarly designed study, crude oil adversely altered corticosterone endocrine functions (Gorsline and Holmes, 1982). Dietary petroleum increased cold stress mortality in saltwater-adapted birds (Holmes *et al.*, 1979). The deaths were attributed to changes in adrenal gland function. A likely mechanism is altered metabolism of steroid hormones in the adrenal gland (Coppock, 2011; Coppock and Dziwenka, 2011). Thyroid activity in nestling tree swallows (*Tachycineta bicolor*) was examined in wetlands partially filled with mine tailings from exploitation of oil sands (Gentes *et al.*, 2007). Compared to control nestlings,  $T_4$  levels in the thyroid gland and plasma levels of  $T_3$  were elevated in nestlings from polluted sites compared to those from the reference site. These findings suggest that endocrine disruption occurred. In a companion study, nestling growth and hepatic ethoxyresorufin-*o*-deethylase (EROD) and nesting success were evaluated (Gentes *et al.*, 2006). Harsh weather was devastating to chicks (48% mortality) on control sites, and polluted sites had 59–100% chick mortality; the odds of chick mortality in the polluted site were 10 times higher. In the subsequent year, with a less harsh weather, chick weights at the polluted sites were less.

The hepatic activity of EROD of chicks on the polluted sites was increased. Xenobiotic-linked up-regulation of hepatic enzymes could be linked to the changes observed in thyroid hormones and could alter steroid metabolism (Coppock, 2011).

## ANALYTICAL TOXICOLOGY

Various analytical techniques can be used to match petroleum oil in the lungs and gastrointestinal tract of an animal with the source of the petroleum. Oil on feathers and fur can also be matched by analytical methods with the source. Petroleum gas in water wells can be matched to the oil- and gas-producing formations in the area. The best procedure is to contact the laboratory and request instructions for appropriate sampling containers and methods of preservation. Care must be taken that lubricants on clippers and other devices do not contaminate the samples. The sampling procedure must be written out, signed, and dated. Labels must correspond with the description of the sample. Pictures should be taken and a log made of the photographs. Glass containers should be used, and the containers must be chemically clean. The majority of samples can be stored by freezing. Care must be taken to ensure that samples do not break during freezing and that the frost on the container during thawing does not alter the label. Plastic containers have the disadvantages that substances may migrate into the sample and they present expensive cleanup problems for the analytical laboratory. If aluminum foil is used to seal containers, the dull side has contact with the sample. Pictures should be taken and a description of the pictures written. The tissues that should be collected at necropsy appropriate for the anatomy of the species include rumen and stomach contents, contents from various areas of the gastrointestinal tract, liver, kidney, lung (including description of the lobe), perirenal or bone marrow fat, brain, and soiled hair or feathers. Samples should be taken of the suspect petroleum. Environmental samples include soil, water with floating substances, and water plus sediment. The suspect water and oil should be sampled. The analytical chemistry is complex because petroleum and the compounds associated with petroleum and oil and gas field operations are complex mixtures of chemicals. The most common approach is to match chromatographic fingerprints. The chromatographs are extracts from tissues such as lung and other tissues and chromatographs of the suspect petroleum. Chemicals in petroleum that are resistant to biodegradation are called biomarker chemicals (e.g., phytane and pristane). Many of the biomarkers in crude petroleum are sensitive to petroleum refining

and upgrading processes. Some biomarkers can have some level of accumulation in fat. The percentage of fat found in tissue extracts must be recorded along with the concentration of the biomarker of interest. If possible, multiple biomarkers should be used and the ratio of the biomarkers calculated for the suspect petroleum and the biomarkers found in tissue. For flare emission issues, analyses of tissues, especially fat, may show the presence of a number of PAHs. However, there are generally multiple sources of these PAHs. In the assay of produced water, ions and heavy metal pollutants can be assayed. In addition to the concentration of the ions or metals, the ratios of the ions and metals can be helpful in identification and tracing the production water to its source. For example, if production water has contaminated domestic water, the ratio of the ions in the domestic water should reflect the ion ratio found in the produced water.

## DIFFERENTIAL DIAGNOSIS

The diagnosis of petroleum toxicity can be straightforward or very difficult, depending on the circumstances. If the exposure is current or recent and there is direct evidence of toxic substances in or on the animals and obvious detrimental effects, the diagnosis may still require careful assessment and testing, but it should be accomplished relatively easily. However, if the exposure has not been recent and clinical signs are not specific or are ones that may have several possible causes, the diagnosis can be very difficult. Pneumonic lesions associated with crude oil toxicity are easier to interpret if oil is still present in the gastrointestinal tract. The presence of vacuolated macrophages is helpful in differentiation from infectious causes of pneumonia. The anatomic site of injury from toxic gases depends on the dose, chemical reactivity, aqueous solubility, and particle size. Water-soluble gases such as  $\text{SO}_2$  usually cause upper respiratory injury. Less soluble gases may cause alveolar injury (Caswell and Williams, 2007). Pneumonia initiated by toxic gases is difficult to diagnose because the initial site of injury is at the bronchoalveolar junction, the same location as the initial site of infection for several viral and bacterial pathogens. The bronchiolitis and alveolar reactions of necrosis, edema, and cellular infiltration can be indistinguishable between toxic gas responses and infectious agent responses. In addition, toxic gases can interfere with the normal functions of cells lining the trachea and bronchi, leading to reduced resistance to infection (Dungworth, 1993). Multiple agents may also be present at the same time, making the determination of the initial cause impossible. Acute neurological signs

may result from sodium ion toxicity. The differential diagnosis includes thiamine deficiency-linked polioencephalomalacia, which results in brain lesions that must be distinguished from those of lead poisoning. The analysis for sodium levels in rumen content is essential. The occurrence of delayed neurotoxicity signs requires an in-depth investigation of potential causes, including TAPs and organophosphorus pesticides, to determine possible exposure. Poor growth and weight loss may have many possible causes, including nutritional deficiency, parasitism, chronic pneumonia, chronic intestinal disease, and mycotoxicosis. Temporal connection to petroleum sources such as crude oil and previous acute cases is important in the differentiation. The possible role of adverse effects of petroleum compounds on the immune system in increasing susceptibility to infectious disease further complicates the situation. Reproductive losses may have multiple causes. The time delay often present between exposure and clinical signs makes diagnosis very difficult, if not impossible. Abortions that result during an acute toxic episode are the easiest to associate with the toxin. The potential hormonal disruption from chemicals that disturb the endocrine hormone system relating to conception and pregnancy may not be possible to determine days or weeks after the exposure.

Signs of irritation of the eyes and respiratory tract may be observed after exposure to irritating gas. The occurrence of ocular and respiratory irritation in the presence of toxic gases is a typical sign. However, similar irritation may result from dry, dusty, and windy conditions and from irritating particles in feed. The measurement of toxic gas levels in the vicinity of the livestock is seldom possible, and assumptions of exposure based on data from the emission source and nearby monitoring sites may be the only data available. Isolating the infectious agent and ruling out toxic gas exposure may make differentiation from infectious pinkeye.

## CONCLUSIONS AND FUTURE DIRECTIONS

Domestic and wild animals ingest petroleum and chemicals used in the exploration and production of oil and gas. Many of the chemicals used have limited toxicology information, and the toxicology of chemical mixtures is unknown. The toxicology in aquatic organisms may be known because of the requirement for toxicology assessments before use on offshore platforms.

Areas that require future research are analytical methods and toxicological assessment in laboratory exposure systems. Definitive toxicology data are required before epidemiological studies can be accurately interpreted.

# Polychlorinated biphenyls, polybrominated biphenyls, polychlorinated dibenzo-*p*-dioxins, and polychlorinated dibenzofurans

Steven Bursian, John Newsted and Matthew Zwiernik

## INTRODUCTION

Polychlorinated biphenyls (PCBs), polybrominated biphenyls (PBBs), polychlorinated dibenzo-*p*-dioxins (PCDDs), and polychlorinated dibenzofurans (PCDFs) form a large group of compounds, the polyhalogenated aromatic hydrocarbons (PHAHs), that are structurally related and are environmentally and biologically persistent (Safe, 1990, 1998; Van den Berg *et al.*, 1994; Fries, 1995; Huwe, 2002; Mandal, 2005; Schecter *et al.*, 2006).

PCBs and PBBs were produced commercially for a variety of applications, whereas the PCDDs and PCDFs occur as byproducts of industrial and natural processes. The structurally similar PCBs and PBBs are formed by substituting chlorine or bromine, respectively, for hydrogen on the biphenyl molecule that consists of two benzene rings (Figure 62.1). Theoretically, there are 209 possible PCB and PBB congeners considering the five chlorine or bromine binding sites on each ring. Each congener is assigned a unique number from 1 to 209 in accordance with the rules of the International Union of Pure and Applied Chemistry (IUPAC). Commercial PCB and PBB products were mixtures of congeners that differed with respect to the extent and positions of chlorination or bromination. PCDDs are composed of two benzene rings connected by two oxygen bridges and contain four to eight chlorines, for a total of 75 congeners (Figure 62.1). PCDFs are also composed of two

benzene rings that are fused to a furan ring in the middle. The benzene rings each have four chlorine binding sites (Figure 62.1). There are 135 different PCDF congeners (DiCarlo *et al.*, 1978; Safe, 1990, 1998; Fries, 1995; Headrick *et al.*, 1999; Huwe, 2002; Mandal, 2005; Schecter *et al.*, 2006; Erickson and Kaley, 2011).

Certain approximate stereoisomers in this group, often referred to collectively as dioxins and dioxin-like compounds (DLCs), induce a common suite of effects and have a common mechanism of action mediated by binding of the PHAH ligand to a specific high-affinity cellular protein. This group of dioxins and DLCs includes 7 PCDD congeners, 10 PCDF congeners, and 12 PCB congeners. Although the PBB congeners analogous to the 12 PCB congeners could also be considered dioxin-like chemicals, the relatively short commercial life span and restricted environmental distribution of PBBs generally preclude them from consideration. The prototype for the dioxins is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD). Toxicity and persistence of the PHAHs are determined by structure, with lateral substitutions on the ring resulting in the highest degree of toxicity. For the PCDDs and PCDFs, congeners with chlorines in the 2, 3, 7, and 8 positions fall into this category. The TCDD-like PCB congeners are the non-*ortho*-substituted compounds with no chlorines on the 2, 2', 6, or 6' position and mono-*ortho*-substituted compounds with no more than one chlorine on the 2, 2', 6, or 6' position (Safe, 1990; Fries, 1995; Headrick *et al.*, 1999; Huwe, 2002; Mandal, 2005; Schecter *et al.*, 2006).

**FIGURE 62.1** Structures and numbering of generic PCB/PBB (top), PCDD (middle), and PCDF molecules (bottom).

Mechanistic studies indicate that the toxic and biochemical effects associated with exposure to TCDD and related PCDDs, PCDFs, and PCBs are mediated by initial binding of the chemical to the cytosolic aryl hydrocarbon receptor (AhR) present in target tissues and organs. There is a correlation between the AhR binding affinity of these chemicals and their structure-toxicity relationships, which supports the idea that the AhR is involved in the mediation of responses induced by TCDD and related PCDD, PCDF, and PCB congeners (Okey *et al.*, 1994; Hahn, 1998, 2002; Safe, 1998; Denison *et al.*, 2002; Denison and Nagy, 2003; Mandal, 2005).

The common mechanism of action of TCDD and related compounds allows for use of the toxic equivalency factor (TEF) approach to estimate the TCDD-like toxicity of complex mixtures containing chemicals that resemble TCDD. The TEF for a TCDD-like congener is a number that reflects the potency of the individual congener relative to TCDD. Using the TEF concept, the total TCDD toxic equivalents (TEQs) for a complex mixture containing TCDD-like chemicals can be calculated to provide an estimation of the total TCDD-like toxicity. Toxic equivalents contributed by each TCDD-like chemical in the mixture are determined by multiplying the concentration of the congener by its TEF (Safe, 1998; Huwe, 2002).

The PCDDs, PCDFs, and PCBs are widely distributed into the global environment due to long-range transport, and they can be very resistant to environmental degradation and metabolism. As a result, they readily accumulate in the food chain, with the greatest tissue concentrations being found in species at the higher

trophic levels. Residues have been detected in a variety of animal species, including humans (Van den Berg *et al.*, 1994; Safe, 1998). In some situations, the environmental concentrations of these contaminants are such that there is a health risk to animals and humans. Because of this risk, there continues to be an effort on the part of state, federal, and international regulatory agencies to minimize exposure to this significant class of environmental contaminants.

## BACKGROUND

### Sources of PCBs, PCDDs, PCDFs, and PBBs

#### PCBs

PCBs were initially synthesized by Schmidt and Schultz in 1881 and were first manufactured commercially in 1929 by the Swann Chemical Company in Anniston, Alabama. In 1935, the Monsanto Company, based in St. Louis, Missouri, purchased the Swann Chemical Company and continued production of Swann's line of polychlorinated polyphenyl products marketed under the trade name of Aroclor. This product line included the widely known PCBs as well as polychlorinated terphenyls (PCTs) and mixtures and blends of PCBs and PCTs. Most PCBs were known as liquid Aroclors, and PCTs and the most highly chlorinated PCBs were known as solid Aroclors. In naming the liquid PCB products, the trade name Aroclor was followed by a four-digit number in which the first two digits were "12," which designated the product as a refined PCB, and the last two digits referred to the average percentage of chlorine, by weight, in the product. For example, Aroclor 1260 was a refined PCB product containing 60% chlorine by weight. Monsanto was responsible for most of the U.S. production of PCBs, which continued until 1977 (Erickson and Kaley, 2011). Similar PCB mixtures were produced by other manufacturers worldwide through the 1980s. Trade names of these products included Clophen (Bayer, Germany), Pheoclor and Pyralene (Prodelec, France), Fenchlor (Caffro, Italy), Kanechlor (Kanegafuchi, Japan), Chlorfen (Poland), Sovol (the former USSR), and Delor (Chemko, the former Czechoslovakia) (Kimbrough, 1987, 1995; Safe, 1994; Erickson and Kaley, 2011).

There were three major use categories of PCBs: completely closed systems (electrical equipment including capacitors and transformers), nominally closed systems (hydraulic and heat transfer systems and vacuum pumps), and open-ended applications (plasticizer in polyvinyl chloride, neoprene, and other chlorinated rubber). PCBs were also components of surface coatings, paints, inks, adhesives, and pesticide extenders. In

addition, they were used for microencapsulation of dyes for carbonless copy paper, immersion oils for microscopes, catalysts in the chemical industry, and as cutting oils and lubricating oils. Capacitors and transformers were the primary uses of PCBs (approximately 50 and 25%, respectively), whereas hydraulic and lubricating fluids accounted for approximately 6% (Safe, 1990; Headrick *et al.*, 1999; Erickson and Kaley, 2011).

The physical and chemical properties of PCBs, such as high stability, inertness, and dielectric properties, that were advantageous for many industrial purposes led to the international use of PCBs in large quantities (Tanabe, 1988). For example, the estimated cumulative production of PCBs in the United States between 1930 and 1975 was 700,000 tons, and an estimated 1.2 million tons were produced worldwide. Domestic sales of PCBs in the United States during this time period totaled 627,000 tons (Kimbrough, 1987, 1995; Tanabe, 1988).

PCBs were identified in environmental media and biota as early as the late 1960s. Some uses of PCBs resulted in environmental releases, such as the recycling of PCB-containing carbonless copy paper. However, the majority of PCBs were sealed in electrical equipment and thus only entered the environment as the result of accidents, maintenance, or disposal after years of service (Erickson and Kaley, 2011). By early 1970, Monsanto started to address the presence of PCBs in the environment, and in 1971 the company voluntarily withdrew PCBs from all markets that were considered likely to lead to environmental discharges. Sales were restricted to a limited number of manufacturers of electrical equipment (capacitors and transformers), which was considered a closed-end use. In 1977, 2 years before the U.S. Environmental Protection Agency's (EPA) ban of the manufacture of PCBs, Monsanto ceased production entirely (Kimbrough, 1987, 1995; Erickson and Kaley, 2011).

Although PCBs are no longer used commercially because of their persistence, they are still present in the environment. Approximately 31% (370,000 tons) of all the PCBs produced is present in the global environment. It is estimated that 780,000 tons are still in use in older electric equipment and other products, deposited in landfills and dumps, or in storage (Tanabe, 1988).

### PCDDs and PCDFs

PCDDs and PCDFs are byproducts that are formed during the synthesis of certain industrial halogenated aromatics chemicals, byproducts from other commercial processes, and byproducts of combustion (Safe, 1990). Some of the important industrial sources of PCDDs and PCDFs have included their formation as byproducts in the production of PCBs, chlorinated phenols and chlorinated phenol-derived chemicals, hexachlorobenzene, technical hexachlorocyclohexanes, and chlorides of

iron, aluminum, and copper. PCDDs and PCDFs have also been identified in effluents, wastes, and pulp samples from the pulp and paper industry and in finished paper products. Emissions from municipal and hazardous waste incinerators as well as home heating systems that use wood and coal, diesel engines, forest and grass fires, and agricultural and backyard burning contain PCDDs and PCDFs. Another contribution might come from naturally formed PCDDs and PCDFs, which have been detected in deep soils and clays from the southern United States and Germany (Safe, 1990; Huwe, 2002).

Historical data suggest that the majority of anthropogenic PCDDs and PCDFs began entering the environment in the 1930s and 1940s, with releases peaking in the 1970s. Since the 1970s, emissions have been decreasing (Bhavsar *et al.*, 2008). EPA estimated that annual emissions of PCDDs and PCDFs decreased from 13.5 to 2.8 kg TEQ/year between 1987 and 1995. This was due primarily to improvements in incinerator performance and removal of incinerators that could not meet emission standards. Other regulations, including bans or restrictions on the production and use of chemicals such as the wood preservative pentachlorophenol (PCP), the phaseout of leaded gasoline that contained halogenated additives, and the elimination of chlorine bleaching in the pulp industry, also contributed to reducing concentrations of PCDDs and PCDFs (Huwe, 2002). There has been a further 50% decline in emissions between 1995 and 2000 from known sources in the United States (Bhavsar *et al.*, 2008).

### PBBs

PBBs were manufactured for use as flame retardants in industrial and consumer products (Damstra *et al.*, 1982). It is estimated that approximately 13 million pounds were produced in the United States from 1970 to 1976 and used by more than 130 companies for incorporation into plastic products that included business machine housings, radios, televisions, thermostats, electric shavers, hand tools, and various automotive parts (DiCarlo *et al.*, 1978; Headrick *et al.*, 1999). Three commercial PBB products were manufactured in the United States: hexabromobiphenyl, octabromobiphenyl, and decabromobiphenyl (DiCarlo *et al.*, 1978; Hardy, 2000). Hexabromobiphenyl was the predominant product, with approximately 11.8 million pounds being produced solely by Michigan Chemical Company (DiCarlo *et al.*, 1978). More than 98% of the hexabromobiphenyl was produced as FireMaster BP-6, with the remainder being produced as FireMaster FF-1 (Hesse and Powers, 1978) after addition of an anti-caking agent to FireMaster BP-6. Michigan Chemical Company stopped production of its PBB products in 1974 (DiCarlo *et al.*, 1978). White Chemical Company and Hexcel Corporation

manufactured octa- and decabromobiphenyl in the United States until 1979 (IARC, 1986). Production of decabromobiphenyl was discontinued in Great Britain in 1977, and Germany stopped production of brominated biphenyls in 1985. In 2000, France discontinued the remaining commercial production of PBBs (Hardy, 2000).

### Environmental fate of PCBs, PCDDs, PCDFs, and PBBs

The release of PCBs into the environment primarily has been the result of leaks, spills, and improper disposal. As stated previously, it is estimated that approximately 370,000 tons of PCBs are present in the global environment (Tanabe, 1988). The volatility of PCBs allows their evaporation from water surfaces and movement through the atmosphere, resulting in widespread environmental dispersal (Headrick *et al.*, 1999).

PCDDs and PCDFs are released into the atmosphere primarily by combustion sources and by evaporation from PCDD/PCDF-containing soils and water. Similar to PCBs, the PCDDs and PCDFs can be transported long distances by winds, contributing both to general background concentrations and to contamination of remote areas far from the original source.

PCBs, PCDDs, and PCDFs are removed from the atmosphere by physical processes such as wet and dry deposition and vapor uptake and are deposited on soils, surface waters, and plant surfaces. Most of the PCBs, PCDDs, and PCDFs that are deposited on surface waters sorb onto suspended sediments. Once bound to soil and sediment, these chemicals generally remain fixed, except for bulk transport due to soil erosion, flooding, and dredging (Dickson and Buzik, 1993). Ingestion of these compounds by animals results in their preferential bioaccumulation and biomagnification in higher trophic levels of the food chain (Safe, 1994).

Because PBBs were manufactured for a relatively short time and because of their restricted use, they are not considered to be a significant environmental contaminant with the exception of specific locations in Michigan related to production and disposal. It is important to remember that the commercial PCB products and PCBs, PCDDs, and PCDFs in environmental extracts are complex mixtures of congeners. Because of various physical and biological processes, the compositions of the commercial PCB mixture and an environmental PCB/PCDD/PCDF mixture may vary significantly from one another. Thus, the impacts of PCBs, PCDDs, and PCDFs on the environment and biota are due to the individual components of these mixtures and their additive and/or non-additive (synergistic/antagonistic) interactions with themselves and other classes of pollutants (Safe, 1994).

### Exposure to PCBs, PCDDs, PCDFs, and PBBs

There are a number of ways by which animals can be and have been exposed to PCBs, PCDDs/PCDFs, and PBBs. Some of the scenarios described involve ingestion of low concentrations of these chemicals through consumption of environmentally contaminated feed or feed components, whereas other scenarios involve accidental incorporation of the chemical into the feed, resulting in exposure to relatively high concentrations of the contaminant. Usually, food animal exposures to PCBs, PCDDs, and PCDFs occur below concentrations resulting in acute toxicity. Clinical signs are not evident, and often there is not a noticeable economic impact on the health of the animal, although there may be detectable contamination of food products such as milk, meat, and eggs (Headrick *et al.*, 1999).

#### PCBs

During the 1940s and 1950s, silos constructed with concrete were sealed with a PCB-containing paint, which eventually peeled off from the walls, resulting in contaminated silage. Dairy and beef cattle were exposed to the paint in the feed, resulting in accumulation of PCBs in adipose tissue. As a result, food products such as milk and meat contained detectable concentrations of PCBs. Examples of other exposure incidents resulting in PCB residues in food animals were summarized by Headrick *et al.* (1999).

#### Michigan PBB incident

The most extensive exposure of food animals and humans to PBBs occurred in Michigan in the mid-1970s. In 1970, the Michigan Chemical Company began to manufacture PBBs under the trade name of FireMaster BP-6 in St. Louis, Michigan. In 1972, the company changed the formulation of the flame retardant and renamed it FireMaster FF-1 (Fries, 1985). In May 1973, 650 pounds of FF-1 was mistakenly included in a shipment of feed-grade magnesium oxide to a feed mill in Climax, Michigan. A portion of the magnesium oxide that was shipped to the feed mill was used to mix feeds primarily for dairy cattle at that location, which were subsequently shipped to area farms or other retail units. The remaining magnesium oxide was shipped to other mills within the state and used in feeds mixed at those locations. Feeds that were not formulated to contain magnesium oxide also became contaminated because of carryover from the contaminated feed-mixing equipment (Fries, 1985). In total, 101 feed mills were affected (Duncel, 1975).

Most of the high-level exposures occurred during the fall of 1973 before sale of the initial batch of feed was

stopped in December 1973 because of dairy producer complaints of animal health problems. Low-level contamination of feed continued beyond the chance identification of PBBs as the contaminant in April 1974 because of their persistence. Because of the long half-life of PBBs, the decision was made to depopulate affected farms and to dispose of the animals at a burial site in northern Michigan. Initially, 9400 head of cattle, 2000 swine, 400 sheep, and 2 million chickens were buried in addition to 865 tons of feed and animal byproducts such as cheese, butter, dry milk products, and eggs. Later, an additional 20,000 head of cattle as well as 3900 swine and 1100 sheep were buried (DiCarlo *et al.*, 1978; Damstra *et al.*, 1982; Fries, 1985; Headrick *et al.*, 1999). In total, 507 farms were affected (Dunckel, 1975).

### PCDDs and PCDFs

For livestock, atmospheric deposition of PCDDs and PCDFs onto forage and soils is assumed to be the major source of exposure (Huwe, 2002). Extensive field studies in contaminated areas have demonstrated a positive correlation between PCDD and PCDF concentrations in animals and their soil contact (Van den Berg *et al.*, 1994). The relative importance of soil depends on the species of animal and the management system. Ruminants are expected to be more vulnerable to PCDD and PCDF exposure than are poultry and swine because of their grazing activities. The use of pasture is of particular importance because consumption of contaminated plants is additive to soil ingestion of PCDDs and PCDFs. Volatilization of PCDDs and PCDFs from soil and deposition on plants is an important pathway of animal exposure when forage is abundant. However, that soil may be more important when grazing is sparse. The soil ingestion pathway is not limited to grazing animals. Cattle confined to unpaved lots consume small amounts of soil that can lead to product residues. Tanabe and Minh (2010) reported that open dumps in developing Asian countries are a potential source of PCBs, PCDDs, and PCDFs. A variety of municipal wastes are disposed of at these sites, where spontaneous low-temperature burning and/or intentionally generated fire are common, resulting in the formation of PCDDs and PCDFs. In addition, PCBs can be leached from old electrical equipment dumped there. Humans residing near the dump sites are at risk from direct exposure to these chemicals, but in some countries, such as India, an additional route of exposure is through consumption of contaminated milk from buffalos and cows that graze on the garbage in the dumps. Although most poultry and pork production is conducted in confined operations, the soil ingestion pathway of exposure may be important when these species have access to contaminated soil (Fries, 1995). Van Overmeire *et al.*

(2009a,b) and Waegneers *et al.* (2009) reported that home-produced eggs in Belgium contained elevated concentrations of PCBs, PCDDs, and PCDFs, which was attributed to consumption of soil and soil organisms by laying hens.

In addition to exposure to PCDDs and PCDFs through consumption of contaminated soil and/or forage, a number of other incidents of animal exposure to these compounds have been reported. The first known exposure to PCDDs occurred in the late 1950s. "Chick edema disease," as the condition was initially called, resulted from consumption of feed containing fat contaminated with a number of PCDD congeners originating from the production of PCP. In 1975, several horses died in Missouri as a result of exposure to TCDD-contaminated waste oil that was used for dust control on horse tracks. In a geographical survey, high concentrations of TEQs in cattle were strongly correlated to PCP-treated wood used for fence posts and feed bunks at several beef cattle operations across 13 states in the United States. Although the use of PCP was restricted in the 1980s, PCP was used heavily on farms as a wood preservative in the late 1970s (Huwe, 2002). In an EPA survey of poultry, samples were found with PCDD concentrations considerably above background. The origin of this contamination was ball clay, which had been added as an anti-caking agent to soy meal in the feed. This same contaminated feed was also used by the catfish industry and resulted in high TEQ concentrations in catfish from Arkansas (Huwe, 2002).

Several dioxin contamination incidents have occurred in Europe. In 1998, during routine monitoring, dairy products were identified that had dioxin concentrations two to four times higher than background concentrations. The source of the contamination was traced to citrus pulp used as a cattle feed component. In another incident, PCB/PCDD/PCDF-contaminated oil was added to recycled fat used as an additive in animal feeds. The affected feeds contaminated Belgian poultry, dairy, and meat and were discovered only after toxic effects characteristic of "chick edema disease" were seen in chickens. Animals and products were quarantined, recalled, and eventually destroyed. The incident led to international recalls and bans of Belgian products (Van Larebeke *et al.*, 2001; Bernard *et al.*, 2002; Huwe, 2002; Guitart *et al.*, 2010). In November 2008, routine sampling of fat from slaughtered pigs in Ireland indicated the presence of non-TCDD-like marker PCB congeners. The source of the contamination was traced to dried bread that had been used as feed. The contaminated dried bread was traced back to a food recycling plant that had used recycled mineral oil as a fuel in direct flame drying of food waste during the processing of animal feed (Casey *et al.*, 2010).

## Differential toxicity

Comparison of the relative toxicities of PCDDs, PCDFs, and PCBs as three separate classes suggests that the dioxins are more toxic than the furans, which in turn are more toxic than the PCBs. It was concluded that PBBs are slightly more toxic than their chlorinated counterparts (McConnell, 1985). Studies also suggest that the toxicity of commercial PCB formulations increases with increasing chlorine content (Aroclor 1221, 1232, 1242, 1248, 1254), but highly chlorinated Aroclors 1260, 1262, and 1268 are less toxic than Aroclor 1254 (Tanabe, 1988).

TCDD binds with the greatest affinity to the AhR and is the most potent congener in terms of toxicity. PCDDs and PCDFs substituted with chlorines in at least three of the four lateral positions (2,3,7,8; Figure 62.1) bind most strongly to the AhR. If chlorines are removed from these lateral positions or if chlorines are added to the nonlateral positions (1,4,6,9; Figure 62.1), binding affinities decrease markedly, as do toxicities. There are seven 2,3,7,8-substituted PCDDs (2,3,7,8-TCDD; 1,2,3,7,8-pentaCDD; 1,2,3,4,7,8-hexaCDD; 1,2,3,6,7,8-hexaCDD; 1,2,3,7,8,9-hexaCDD; and 1,2,3,4,6,7,8-heptaCDD and -octaCDD) and ten 2,3,7,8-substituted PCDFs (2,3,7,8-TCDF; 1,2,3,7,8-pentaCDF; 2,3,4,7,8-pentaCDF; 1,2,3,4,7,8-hexaCDF; 1,2,3,6,7,8-hexaCDF; 1,2,3,7,8,9-hexaCDF; 2,3,4,6,7,8-hexaCDF; 1,2,3,4,6,7,8-heptaCDF; and 1,2,3,4,6,7,8-heptaCDF and -octaCDF) that induce TCDD-like toxicity. There are 209 theoretically possible PCB congeners having different toxic and biologic responses. The most toxic PCB congeners have four or more chlorine atoms at both the *para* (4,4') and the *meta* positions (3,3',5,5'; Figure 62.1) in the biphenyl rings, but they have no chlorine (bromine) atoms in the *ortho* positions (2,2',6,6'; Figure 62.1). Of the 209 PCB congeners, four (3,3',4,4'-tetraCB (IUPAC 77); 3,4,4',5-tetraCB (IUPAC 81); 3,3',4,4',5-pentaCB (IUPAC 126); and 3,3',4,4',5,5'-hexaCB (IUPAC 169)) are approximate stereoisomers of the highly toxic TCDD and thus bind to the AhR and elicit toxic and biologic responses typical of TCDD, although at higher doses. These 4 congeners are considered to be coplanar because both rings of the biphenyl molecule lie in the same plane, which enables binding to the AhR (Tanabe, 1988). There are 8 PCB congeners with chlorine substitution in one of the *ortho* positions (2,2',6,6'). These congeners may have partial coplanarity and thus exhibit lower competitive binding affinities for the AhR and lower toxic potency. The mono-*ortho* PCB congeners are 2,3,3',4,4'-pentaCB (IUPAC 105); 2,3,4,4',5-pentaCB (IUPAC 114); 2,3',4,4',5-pentaCB (IUPAC 118); 2',3,4,4',5-pentaCB (IUPAC 123); 2,3,3',4,4',5-hexaCB (IUPAC 156); 2,3,3',4,4',5-hexaCB (IUPAC 157); 2,3',4,4',5,5'-hexaCB (IUPAC 167); and 2,3,3',4,4',5,5'-heptaCB (IUPAC 189) (Poland and Knutson, 1982; Tanabe, 1988; Safe, 1990, 1998; Giesy and Kannan, 1998; Huwe, 2002; Whyte *et al.*, 2004).

## TEFs

The relationship between the structure of individual PCDD, PCDF, and PCB congeners and their toxicity is the basis of TEFs and the TEQ approach. The TEQ approach is used to determine the toxic potency of complex mixtures of PCDDs, PCDFs, and PCBs found in the environment. Assuming a similar mechanism of action (binding to the AhR), the potency of each chemical in a mixture to cause a particular toxic or biological effect can be expressed as a fraction of the potency of TCDD to cause the same effect. Thus, the TEF is a ratio of  $EC_{50}$  (TCDD-like chemical)/ $EC_{50}$  (TCDD). TCDD has been assigned a TEF value of 1.0. Based on a variety of biological endpoints, relative potency factors (RPFs) are assigned to the different TCDD-like congeners. All RPFs for an individual congener are evaluated to derive a consensus value (the TEF) that describes an order-of-magnitude potency for that congener. The toxic potency of a mixture of PCDDs, PCDFs, and/or PCBs is estimated by multiplying the concentrations of individual congeners by their respective TEFs and summing the products to yield total TEQs. The total TEQs express the toxicity as if the mixture were pure TCDD (Safe, 1990, 1998; Dickson and Buzik, 1993; Van den Berg *et al.*, 1994, 2006; Fries, 1995; Whyte *et al.*, 2004; Schecter *et al.*, 2006). Several assumptions are made when using the TEF approach: (1) the effects of individual PCDDs, PCDFs, and/or PCBs in a mixture are additive; (2) only tissue and environmentally persistent organochlorine compounds have been assigned TEFs; and (3) all of these compounds bind to the AhR and elicit receptor-mediated biochemical and toxic responses (Safe, 1998). The TEQ approach and current values (Table 62.1) have been adopted internationally as the most appropriate way to estimate the potential health risk of mixtures of TCDD-like chemicals (Schecter *et al.*, 2006).

There are some limitations with the TEF approach. Blankenship *et al.* (2008) note that TEFs are consensus values of relative potencies of the various PCB/PCDD/PCDF congeners rather than precise values. They may vary depending on species, measurement endpoint, and the relative proportions of individual congeners in complex mixtures. The assumption that toxic responses to TCDD-like chemicals are additive and that other classes of contaminants do not modify or add to the toxicity clearly is not always correct (Safe, 1998). In addition, some of the mammalian TEFs are based on *in vitro* studies that do not account for whole animal exposure characteristics, including absorption, distribution, metabolism, and elimination, or on quantitative structure-activity relationships because of a lack of toxicity data for some congeners, which can introduce an additional degree of uncertainty into the determination of TEQs. Another limitation of the TEF approach is that it does not consider potential adverse effects of *ortho*-substituted PCB

TABLE 62.1 Summary of World Health Organization (WHO) 2005 toxic equivalency factor (TEF) values

Compound	WHO 2005 TEF
<i>Chlorinated dibenzo-p-dioxins</i>

From Van den Berg *et al.* (2006).

congeners. *Ortho*-substituted PCBs have been shown to elicit a variety of non-AhR-mediated toxic responses in experimental animals, including neurobehavioral, neurotoxic, carcinogenic, and endocrine changes. However, studies reviewed by Giesy and Kannan (2002) suggest that it is unlikely that the effects of *ortho*-substituted PCBs are critical to survival at concentrations typically associated with the AhR-mediated toxic effects of PCBs.

## TOXICOKINETICS

### PCBs and PBBs

Because commercial PCB and PBB products are mixtures of individual congeners that differ in the number and position of chlorine or bromine atoms and thus differ in terms of their biological activities, it is difficult to accurately assess their absorption, distribution, metabolism,

and elimination. A number of experiments have been conducted with a variety of species, including cows, pigs, rats, and birds, on the absorption, distribution, metabolism, and elimination of the commercial PBB mixture FireMaster BP-6, and these were summarized in an extensive review by Fries (1985). Because of the similarities between PCBs and PBBs, information pertaining to one can generally be applied to the other.

In general, PBBs are rapidly and extensively absorbed, with absorption being inversely dependent on the number of bromine atoms (Damstra *et al.*, 1982; Fries, 1985). For example, less than 10% of a dose of C<sup>14</sup>-labeled 2,2',4,4',5,5'-hexabromobiphenyl was eliminated in rats (Matthews *et al.*, 1977; Fries, 1985), indicating almost complete absorption, compared to 62% fecal elimination of C<sup>14</sup>-labeled octobromobiphenyl 24 h after dosing, suggesting incomplete absorption (Norris *et al.*, 1975; Fries, 1985).

PBBs are widely distributed throughout the body of all species studied. Initial concentrations are generally greatest in the liver and adipose tissue (Damstra *et al.*, 1982; Fries, 1985), with highest equilibrium concentrations on a wet tissue basis being in adipose tissue (Miceli and Marks, 1981; Damstra *et al.*, 1982; Fries, 1985). Concentrations of PBBs in muscle and organ tissues are usually an order of magnitude lower than those in adipose tissue. Generally, differences in concentration between tissues can be attributed, at least in part, to variations in fat content of the tissues (Fries, 1985).

Individual PBB congeners in FireMaster BP-6 undergo hydroxylation by metabolic routes that are similar for the related PCBs, with the rate of metabolism being determined primarily by the position of bromine atoms on the ring and secondarily by the bromine content of the molecule (Damstra *et al.*, 1982). *In vivo* studies suggest that, as for PCBs, metabolism can occur if there are two adjacent unbrominated positions (Matthews *et al.*, 1978; Fries, 1985).

Elimination of individual PBB congeners occurs at different rates, with congeners that are more slowly removed becoming more concentrated in tissues relative to congeners that are more rapidly eliminated. The predominant congener in FireMaster BP-6, 2,2',4,4',5,5'-hexabromobiphenyl is the most persistent congener in the various species studied (Damstra *et al.*, 1982). PBBs are eliminated primarily by biliary excretion into the feces, but fecal concentrations are low compared to whole-body concentrations (Damstra *et al.*, 1982; Fries, 1985). Placental transfer of PBBs occurs to some extent, but the concentrations in fetal or offspring tissues are relatively small compared to concentrations in maternal tissues. Transfer of PBBs to the offspring during nursing results in much greater whole-body concentrations compared to PBB transfer during gestation. For example, pigs from sows that were fed PBBs during gestation and lactation had a fivefold increase in body burden during

the 4-week lactation period, with residues accumulated during lactation accounting for 95% of the total body burden (Werner and Sleight, 1981; Fries, 1985).

As suggested previously, milk is the major route of elimination of PBBs for lactating mammals, although in the case of females nursing their young, the contaminant is simply transferred from one animal to another. Concentrations of PBBs in milk fat generally exceed dietary concentrations, with bovine milk fat concentrations exceeding dietary concentrations by three- or four-fold (Fries and Marrow, 1975; Willett and Irving, 1976; Damstra *et al.*, 1982; Fries, 1985).

The egg is a major route of elimination for egg-laying birds, with concentrations in chicken or Japanese quail eggs being 1 to 1.5 times that of dietary concentrations (Babish *et al.*, 1975; Fries *et al.*, 1976; Polin and Ringer, 1978a; Damstra *et al.*, 1982; Fries, 1985). Elimination of PBBs via the egg can account for as much as 50% of the daily dose if there is no deleterious effect on egg production (Fries, 1985).

PBBs can have a relatively long biological half-life in animals. Studies with cows suggested biphasic elimination of PBBs via the milk, with an initial half-life of 11 days and a second half-life of 58 days (Fries and Marrow, 1975; Gutenmann and Lisk, 1975; Fries *et al.*, 1976; DiCarlo *et al.*, 1978). In cases in which observation periods were long, a biological half-life of 180 days was estimated for lactating cows (Fries, 1985). It was estimated that the concentration of FireMaster BP-6 in bovine milk fat would decrease from approximately 300 to 0.3ppm in 120 weeks (Detering *et al.*, 1975; DiCarlo *et al.*, 1978). A half-life of 17 days was calculated for FireMaster FF-1 in the eggs of chickens fed a diet containing the commercial mixture. It was estimated that a chicken exposed to 1ppm PBB in the feed for at least 10 days (the minimum time required to attain a steady-state concentration in the contents of a whole egg) would require 87 days of feeding uncontaminated feed to reach a concentration of 0.05ppm in the whole egg (Ringer and Polin, 1977).

## PCDDs and PCDFs

The absorption, distribution, metabolism, and elimination of PCDDs and PCDFs have been extensively reviewed by Van den Berg *et al.* (1994). Absorption from the gastrointestinal tract of mammals is effective and can exceed 75% of the dose for the lower chlorinated congeners. With increasing molecular size, absorption from the intestines is greatly reduced, which is most apparent for the hepta- and octachlorinated congeners. The liver and adipose tissue are the major storage sites of PCDDs and PCDFs for most mammalian and avian species. The biotransformation of PCDDs and PCDFs depends on the

number and position of the chlorine atoms on the molecule. Metabolic reactions include oxidation and reductive dechlorination as well as breakage of the oxygen bonds. Sulfur-containing metabolites have also been identified. In general, the urinary and biliary elimination of 2,3,7,8-substituted congeners depends on the metabolism of these compounds. Whole-body half-lives of the group of 2,3,7,8-substituted congeners in rodents range from a few to more than 100 days.

The absorption of PCDDs and PCDFs from the gastrointestinal tract has been studied for a number of individual congeners. The extent of absorption of 2,3,7,8-TCDD or related compounds is variable, depending on the vehicle and the substitution pattern of the congener. There appear to be no differences between species in terms of absorption of these compounds through the gastrointestinal tract. There are indications that passage across the intestinal wall is predominantly limited by molecular size and solubility, with the influence of these two parameters being most significant for hepta- and octachlorinated congeners, which exhibit decreased absorption. Studies with rats, mice, hamsters, guinea pigs, cows, and chickens in general indicate that 2,3,7,8-tetra- and pentachlorinated congeners are well absorbed from the gastrointestinal tract (50–90%), and octachlorodibenzo-*p*-dioxin is absorbed only to a limited extent (2–15%) (Pohjanvirta and Tuomisto, 1994; Van den Berg *et al.*, 1994).

The tissue distribution of PCDDs and PCDFs has been extensively studied in laboratory experiments using rodents and nonhuman primates. The liver and adipose tissue are the major storage sites of PCDDs and PCDFs for most mammalian and avian species, whereas depending on species, the skin and adrenals can also act as primary sites for deposition. Several studies with rats, mice, hamsters, guinea pigs, and monkeys indicated that the 2,3,7,8-substituted PCDDs and PCDFs are the predominant congeners retained in tissues and body fluids. Studies suggest that the tissue distribution of TCDD and related compounds is dose dependent in that as the dose increases, so does the liver:adipose distribution ratio. In the liver, TCDD induces both cytochromes CYP1A1 and CYP1A2. Induced CYP1A2, in turn, appears to be a crucial binding species for TCDD and related compounds in rodents. The hepatocellular binding of TCDD to CYP1A1 is so strong that only a very limited amount will be released back into the circulation. Placental transfer of 2,3,7,8-substituted PCDDs and PCDFs was found to be strongly dependent on molecular size. In a number of mammalian species, the transfer of PCDDs and PCDFs from the mother to the offspring via lactation is quantitatively more important than transport to the fetus across the placenta. Excretion via lactation generally decreases as chlorine content increases (Pohjanvirta and Tuomisto, 1994; Van den Berg *et al.*, 1994).

As in mammals, the liver and adipose tissue of avian species are the major sites for storage and accumulation of 2,3,7,8-substituted PCDDs and PCDFs. Hepatic deposition of 2,3,7,8-substituted PCDDs and PCDFs appeared to increase with increasing chlorination, resulting in a limited transfer of the more highly chlorinated congeners to the egg (Van den Berg *et al.*, 1994).

Metabolism of TCDD and related compounds is necessary for urinary and biliary elimination, thus playing a major role in regulating the rate of excretion of these compounds. In rats, metabolic reactions include oxidation, preferably in the lateral positions, and reductive dechlorination as well as oxygen bridge cleavage of the diphenyl ether in 2,3,7,8-substituted PCDDs. Metabolism of PCDDs and PCDFs is generally thought to be a detoxification process; thus, toxicity is attributable to the unchanged parent compound (Pohjanvirta and Tuomisto, 1994).

The induction of CYP1A1 and CYP1A2 enzyme activities by 2,3,7,8-substituted PCDDs and PCDFs has been shown to be one of the most sensitive parameters for biological activity of these compounds. The enzymes most studied are the CYP1A1-dependent ethoxyresorufin-*ortho*-deethylase and aryl hydrocarbon hydroxylase. In addition, 2,3,7,8-substituted PCDDs and PCDFs also induce phase II enzymes (Van den Berg *et al.*, 1994).

In mammals, the liver and adipose tissue are the major compartments for the deposition of PCDDs and PCDFs. The elimination of polar metabolites of 2,3,7,8-substituted PCDDs and PCDFs occurs predominantly via the bile and feces, with urinary excretion playing a minor role. However, urinary elimination plays an important role in the hamster. In rats, the whole-body half-lives of PCDDs and PCDFs range from 17 to 31 days, depending on the dose and strain of rat used, whereas in hamsters and mice, the whole-body half-lives range from 11 to 15 and from 11 to 24 days, respectively. In rats, it was shown that lactation can reduce the half-life of these compounds, whereas egg-laying can reduce the half-life in avian species. In lactating cows, mean half-lives ranged from 40 to 50 days for tetra- to heptaCDDs and CDFs. 2,3,7,8-Tetrachlorodibenzofuran (TCDF) is eliminated more rapidly than TCDD, having a whole-body half-life of 2 days. The rapid elimination of TCDF is thought to be due to its rapid metabolism. In contrast, 2,3,4,7,8-pentaCDF (PeCDF) is eliminated very slowly in the rat, with a whole-body half-life of 64 days. The slow elimination rate is probably due to tight binding of this congener by CYP1A2, in addition to limited metabolism. As chlorine content increases, the rate of elimination of PCDDs and PCDFs decreases (Pohjanvirta and Tuomisto, 1994; Van den Berg *et al.*, 1994).

Interspecies differences in toxicity can only be partly explained by differences in toxicokinetics. The hamster is the species most resistant to the acute toxicity of TCDD.

Although the elimination rate of TCDD is 2- or 3-fold greater in the hamster than in the rat and mouse, this does not entirely explain the 10- to 100-fold difference in acute toxicity between the hamster and other rodent species. The guinea pig is most sensitive to the acute effects of TCDD, and it is the species with the slowest metabolism and elimination of TCDD, suggesting that toxicokinetics in part explains the unique sensitivity of the guinea pig to the acute toxicity of TCDD and TCDF (Van den Berg *et al.*, 1994).

## MECHANISM OF ACTION

The AhR is a ligand-activated transcription factor that is involved in the regulation of a number of genes, including those for enzymes that play a role in the metabolism of xenobiotics as well as genes involved in cell growth regulation and differentiation (Okey *et al.*, 1994; Safe, 1994; Hahn, 1998, 2002; Denison *et al.*, 2002; Denison and Nagy, 2003; Mandal, 2005). The AhR plays an important role in the altered gene expression and species- and tissue-specific toxicity resulting from exposure to specific PCB, PCDD, and PCDF congeners. It is well established that the majority of the toxic effects attributed to TCDD and TCDD-like chemicals require activation of the AhR. The toxicity of individual congeners is closely related to the affinity with which these compounds bind to the AhR, with the most toxic compounds being those that bind with the greatest affinity (Okey *et al.*, 1994). There are large species and strain differences in sensitivity to TCDD and related chemicals. Mouse and rat strain differences in sensitivity to TCDD can be partially explained by differences in the ligand binding affinity of their polymorphic AhR variants. A study in birds indicated that species differences in sensitivity to TCDD and related chemicals could be due, at least in part, to differences in amino acid composition of the ligand binding domain of the AhR (Karchner *et al.*, 2006). However, differences in AhR concentration or binding affinity do not fully explain the differences in species susceptibility to TCDD and TCDD-like chemicals (Denison *et al.*, 1986).

The AhR is a basic helix-loop-helix (bHLH) and Per-Arnt-Sim (PAS) containing transcription factor (Denison *et al.*, 2002; Denison and Nagy, 2003; Bradshaw and Bell, 2009). In the absence of a ligand, AhR occurs as a soluble multiprotein complex in the cytosol of the cell. The chaperone proteins are two molecules of hsp90 (a heat shock protein of 90 kDa), the X-associated protein 2 and p23 (a co-chaperone protein of 23 kDa). When TCDD or another ligand diffuses across the plasma membrane and binds to the AhR, the ligand AhR complex undergoes a

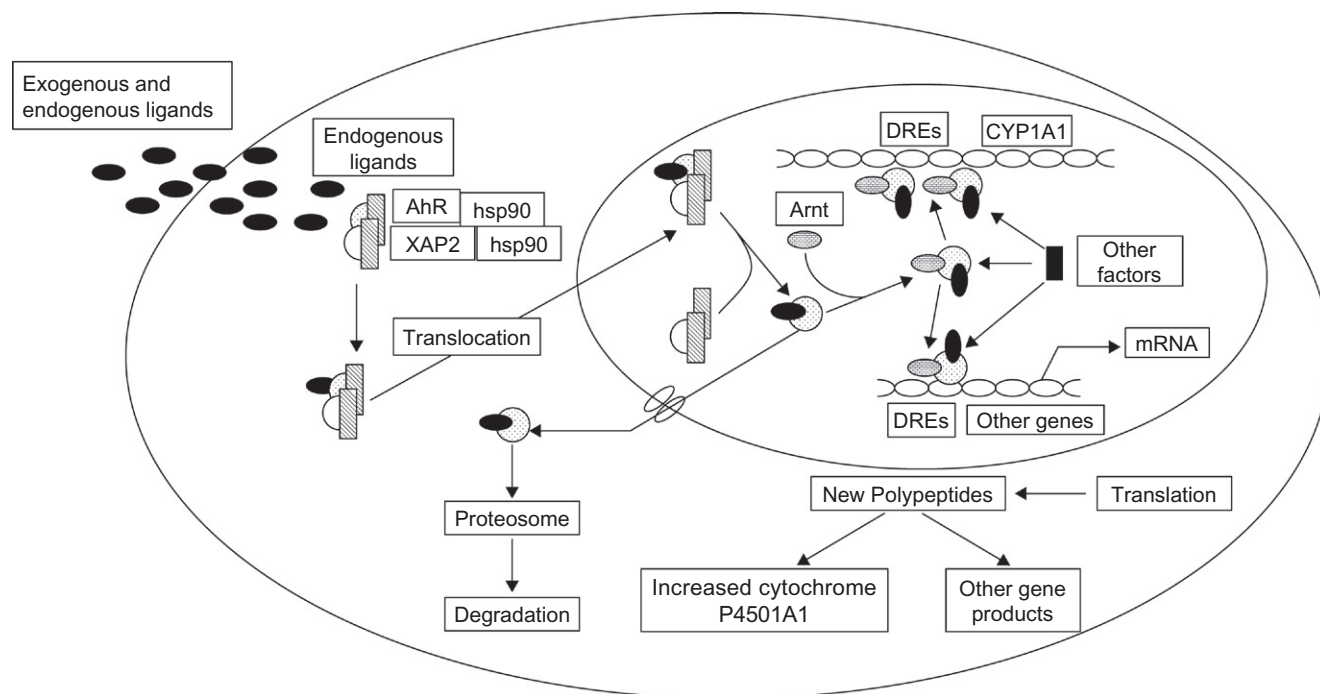

FIGURE 62.2 The proposed molecular mechanism of action of 2,3,7,8-TCDD and TCDD-like chemicals. See text for details.

conformational change that exposes a nuclear localization sequence (Figure 62.2). The complex translocates into the nucleus of the cell, and the chaperone proteins dissociate from the complex. The AhR–ligand then binds to the bHLH–PAS nuclear protein, AhR nuclear translocator, or Arnt. The formation of this heterodimer initiates conversion of the complex into a form that binds to DNA with high affinity on a specific recognition site called the dioxin responsive element (DRE). Binding of the ligand–AhR–Arnt complex to the DRE stimulates transcription of genes encoding cytochrome P450 enzymes in the CYP1A1 subfamily and other AhR-responsive genes that are located upstream of the DRE (Denison *et al.*, 2002; Denison and Nagy, 2003). Continuous and inappropriate modulation of gene expression is thought to be responsible for a series of biochemical, cellular, and tissue changes that result in toxicity characteristic of TCDD and related compounds (Denison and Heath-Pagliuso, 1998; Mandal, 2005).

## TOXICITY

### PBBs

None of the effects caused by PBBs are unique to this particular group of brominated congeners, but they are

characteristic of polyhalogenated hydrocarbons, including PBBs, PCBs, PCDDs, and PCDFs. The acute oral LD<sub>50</sub>s of FireMaster BP-6 as well as octabromobiphenyl and decabromobiphenyl are 2–22 g/kg body weight for a number of species. Death resulting from acute exposures can occur up to 2 weeks after dosing (DiCarlo *et al.*, 1978; Fries, 1985). In general, prolonged exposure to low concentrations of PBBs causes more deleterious effects than does exposure to a large, single dose (Damstra *et al.*, 1982). In most toxicity studies conducted with PBBs, the characteristic effects were a decrease in feed consumption with a concomitant decrease in body weight loss or body weight gain, which may not be entirely related to the decrease in feed consumption. Milk production and egg production may also decrease as a result, at least in part, of reduced feed consumption. The most prominent gross morphological and histological changes occurred in the liver of most species examined, with the exception of cattle, in which the kidney appeared to be the target organ (Damstra *et al.*, 1982; Fries, 1985). Hepatic lesions were characterized by swelling and vacuolation of hepatocytes with fatty infiltration (Corbett *et al.*, 1978; Kimbrough *et al.*, 1978; Gupta and Moore, 1979; Gupta *et al.*, 1981; Fries, 1985). Renal lesions in cattle included dilatation of collecting ducts and convoluted tubules as well as degeneration of tubular epithelium (Moorehead *et al.*, 1977; Fries, 1985). Both the thymus and the avian bursa of Fabricius decreased in size in

some species at relatively low doses. There is a loss of cells specific to the respective tissue and a disruption of the normal architecture (Gupta and Moore, 1979; Gupta *et al.*, 1981; Dharma *et al.*, 1982; Fries, 1985). In addition to reported atrophy of lymphoid tissues in a variety of species, there is evidence that exposure to PBBs causes suppression of the immune system (Moorehead *et al.*, 1977; Kimbrough *et al.*, 1978; Gupta and Moore, 1979; Gupta *et al.*, 1981, 1983; Fries, 1985). However, doses sufficient to cause other toxic effects are usually required to induce immunosuppression, and there appears to be differences between species in terms of sensitivity (Damstra *et al.*, 1982; Fries, 1985). A number of studies have demonstrated PBB-induced reproductive effects in a variety of species, including chickens (Ringer and Polin, 1977; Polin and Ringer, 1978b), Japanese quail (Babish *et al.*, 1975), rats (Corbett *et al.*, 1975; Beaudoin, 1977; Damstra *et al.*, 1982), mice (Corbett *et al.*, 1975; Preache *et al.*, 1976; DiCarlo *et al.*, 1978; Damstra *et al.*, 1982), rhesus monkeys (Allen and Lambrecht, 1978; Damstra *et al.*, 1982), and mink (Aulerich and Ringer, 1979). Commercial PBB mixtures have been shown to cause liver cancer in rats and mice (Kimbrough *et al.*, 1978, 1981; Damstra *et al.*, 1982; Gupta *et al.*, 1983; Fries, 1985).

### PCBs, PCDDs, and PCDFs

Exposure to PCBs, PCDDs, and PCDFs has been linked to a broad spectrum of effects, both *in vivo* and *in vitro*, that vary depending on method/age of exposure, sex of the individual, and dose/duration of exposure (Safe, 1994; Steinberg *et al.*, 2008). The majority of effects caused by commercial PCB mixtures are the same as those induced by TCDD because the responses caused by commercial PCB mixtures are due, in part, to the individual non-*ortho* coplanar and mono-*ortho* coplanar PCBs present in these mixtures that act as AhR agonists. Because some of the mono-*ortho* coplanar PCBs are present in relatively high concentrations in commercial mixtures and environmental extracts, this class of PCBs may contribute significantly to the TCDD-like activity of PCB mixtures (Safe, 1994).

A number of reports describe the common effects induced by TCDD and related PCDDs, PCDFs, and PCBs. The only major difference in these compounds is their relative toxic potencies. These effects are mediated through initial binding of the ligand to the AhR and are dependent on dose, age, sex, species, and strain of animal. In most cases, if a given species is more sensitive to a given class of compound (e.g., PCBs), this species will also be sensitive to the other classes (PCDDs and PCDFs). It has also been observed that in most instances, young animals are more sensitive than adults and females more sensitive than males. In

general, chickens, guinea pigs, and mink are the most sensitive species of animals to the toxic effects induced by 2,3,7,8-TCDD and TCDD-like chemicals. In contrast, hamsters and amphibians appear to be fairly resistant to the toxic effects. The effects include acute lethality, wasting syndrome, thymic and splenic atrophy, impairment of immune responses, hepatotoxicity and porphyria, chloracne and related dermal lesions, tissue-specific hypo- and hyperplastic responses, disruption of multiple endocrine pathways, carcinogenesis, teratogenicity, and reproductive toxicity (Poland and Knutson, 1982; McConnell, 1985; Safe, 1986, 1990, 1998; Dickson and Buzik, 1993; Fries, 1995; Giesy and Kannan, 1998; Schecter *et al.*, 2006).

TCDD causes lethality at very low doses in specific species. The oral LD<sub>50</sub> values for various species are as follows: 0.6–2.0 µg/kg body weight for the guinea pig, 22–45 µg/kg for the rat, 25–50 µg/kg for the chicken, 70 µg/kg for the monkey, 115 µg/kg for the rabbit, 100–200 µg/kg for the dog, 114–284 µg/kg for the mouse, and 1157–5000 µg/kg for the hamster (Safe, 1990). There is a delayed appearance of lethality, irrespective of dose. Death typically does not occur earlier than 1 week after exposure, and it may not occur until 6 weeks of exposure. Before death, the exposed animal generally undergoes a rapid and substantial weight loss called “wasting syndrome” (McConnell, 1985; Pohjanvirta and Tuomisto, 1994). This is accompanied by decreased food and water intake, which accounts for some, but not all, of the weight loss. These may be the only signs observed in rats, mice, guinea pigs, mink, and poultry after oral administration. However, skin lesions have been reported in hairless mice, and acne-like lesions have been described in the ears of rabbits after local application. Occasionally, poultry may show an increase in body weight prior to death due to accumulation of body fluids (subcutaneous edema, ascites, hydrothorax, and hydropericardium). In addition to body weight loss, the clinical syndrome in monkeys and cattle is characterized by skin and eyelid lesions and abnormal growth of finger- or toenails or hooves. The lesions in monkeys are follicular dermatitis (acne) of the face, neck, and forearms; enlarged tortuous Meibomian glands in the eyelid; and overgrowth and loss of nails of the hands and feet. Alopecia may be present, particularly in the areas of the body showing dermatitis. The skin of cattle is thickened and dry, particularly over the neck, shoulders, and back (McConnell, 1985).

TCDD is a highly immunosuppressive chemical in laboratory animals. Effects include decreased host resistance to infectious disease and suppressed humoral and cell-mediated immune responses. Both pre- and post-natal exposure of mice and guinea pigs reduced both the delayed hypersensitivity and lymphoproliferative response. TCDD appears to selectively interfere with

antigen-specific activation of T cells. In addition to immune suppression, TCDD promotes inflammatory responses (Dickson and Buzik, 1993; Pohjanvirta and Tuomisto, 1994; Mandal, 2005).

Thymic atrophy is one of the most uniform and consistent findings in TCDD-exposed mammals. It consists of depletion of small immature cortical thymocytes, making a distinction between cortex and medulla difficult. Although both pyknotic and scattered necrotic lymphocytes have been reported, frank necrosis is not a typical feature of the lesion. At less toxic doses, the thymus might look normal histopathologically while being one-half normal size (McConnell, 1985; Pohjanvirta and Tuomisto, 1994).

TCDD exposure results in hepatomegaly in all species investigated, but there is extensive variation among species in the severity of this lesion. The changes in the liver are accompanied by altered liver function characterized by enzyme induction, porphyria, impaired plasma membrane function, and hyperlipidemia. Liver lesions are most severe in the rabbit, which displays extensive necrosis. In other species, such as the rat, mouse, mink, and, to a lesser extent, the guinea pig, hamster, bovine, and monkey, the predominant features are hepatocellular hypertrophy, multinuclear hepatocytes, steatosis, and inflammatory cell infiltration, often accompanied by scattered focal necrosis with a preferentially centrilobular location. Female rodents are more susceptible to the hepatic effects of TCDD compared to males (McConnell, 1985; Dickson and Buzik, 1993; Pohjanvirta and Tuomisto, 1994; Safe, 1994).

Intrahepatic bile duct hyperplasia has been described in rodents and monkeys, but it is a more prominent feature in chronically exposed animals. Marked epithelial proliferation of the extrahepatic bile duct and gallbladder has been described in monkeys and cattle. Epithelial erosions, ulcers, and inflammation are characteristic components of the lesion. Hyperplasia of the epithelium lining of the urinary tract has been described in guinea pigs, cattle, and monkeys. The lesion extends from the renal pelvis to the urinary bladder, stopping at the level of the urethra. Monkeys exposed to TCDD-like compounds develop a lesion referred to as "simian gastropathy." In acute lethal exposures, the chief (acid-producing) cells are replaced by hyperplastic mucous-producing cells. In more chronic exposures, the hyperplastic change becomes more pronounced and at times appears to invade adjacent tissues. A similar but much less severe lesion has been described in rats exposed to PBBs. The large intestine also shows hyperplastic changes in monkeys chronically exposed to these chemicals (McConnell, 1985).

The skin and associated structures in monkeys, rabbits, and certain strains of mice show characteristic lesions as a result of exposure to TCDD and related

chemicals. In monkeys, the lesion is characterized microscopically by mild epithelial hyperkeratosis and severe atrophy of sebaceous glands and hyperkeratosis of their ducts. The ducts become occluded with keratinaceous debris and grossly the lesion mimics an acne-like lesion. A similar lesion is observed in the Meibomian glands of the eyelid and ceruminous glands of the external auditory canal. Alopecia, dry scaly skin, and fingernail loss are also features of exposure in monkeys. Although most strains of mice do not show skin lesions, certain "hairless" strains show a similar skin lesion as that in monkeys. The inner surface of a rabbit's ear also develops acne-like lesions if the compound is applied directly to the skin. Cattle also show a characteristic skin disease when exposed to these compounds (McConnell, 1985; Safe, 1994).

TCDD and related chemicals reduce serum thyroxine ( $T_4$ ) concentrations rapidly in rats. Changes in  $T_4$  concentrations in other species are less consistent. The decrease in serum  $T_4$  concentrations is thought to be due to accelerated clearance of the hormone. In addition to altering thyroid hormone concentrations, TCDD appears to modulate the concentration of thyroid hormone receptors. Other endocrine changes include alterations in corticosteroid concentrations and in the concentrations of hormones associated with the reproductive system in rodents, monkeys, and birds (Pohjanvirta and Tuomisto, 1994; Safe, 1994; Brouwer *et al.*, 1998; Ulbrich and Stahlmann, 2004).

It is assumed that the interaction of TCDD with the AhR regulates a number of genes, although CYP1A1 has been studied most thoroughly. Thus, in addition to monooxygenases dependent on cytochrome P4501A1, a number of other enzymes are induced (Pohjanvirta and Tuomisto, 1994; Huwe, 2002).

Effects on the nervous system are manifested as hyperactivity, impaired learning, changes in gender-related behavior, and changes in brain neurochemical concentrations in rats, mice, and monkeys (Safe, 1994; Chen and Hsu, 1994; Schantz *et al.*, 1995; Rice, 1999; Berger *et al.*, 2001; Wang *et al.*, 2002; Salama *et al.*, 2003; Ulbrich and Stahlmann, 2004; Branchi *et al.*, 2005).

TCDD and approximate stereoisomers have been shown to affect female reproductive endpoints in a variety of animal studies. Among the effects reported are a decrease in the number of females mated in rats, mink, and monkeys; fewer completed pregnancies in rats, mink, and monkeys; lower maternal weight gain during pregnancy in rats, rabbits, and monkeys; decreased litter size in rats, rabbits, mink, and swine; effects on external genitalia and gonads in rats, mice, and guinea pigs; altered estrous and menstrual cycles in rats, mice, and monkeys; and delayed maturation of the mammary gland and increased incidence of breast cancer in rats and mice. Decreased egg production and hatchability occur in a number of avian species. Numerous

studies have indicated that TCDD and related chemicals are anti-estrogenic presumably due to increased metabolism of estrogen and a decreased number of estrogen receptors (Golub *et al.*, 1991; Ronnback, 1991; Peterson *et al.*, 1993; Safe, 1994; Brown and Lamartiniere, 1995; Gray and Otsby, 1995; Gray *et al.*, 1997; Brown *et al.*, 1998; Fenton *et al.*, 2002; Ishimura *et al.*, 2002a,b; Muto *et al.*, 2002; Salisbury and Marcinkiewicz, 2002; Vorderstrasse *et al.*, 2004; Fenton, 2006; Jablonska *et al.*, 2010). In males, TCDD and related compounds decrease testis and accessory sex organ weight, cause abnormal testicular morphology, decrease spermatogenesis, and reduce fertility when given to adult animals in doses sufficient to reduce feed intake and/or body weight. Some of these effects have been reported in chickens, rhesus monkeys, goats, guinea pigs, rats, and mice treated with overtly toxic doses of TCDD or TCDD-like chemicals. Effects of TCDD on the male reproductive system are thought to be due in part to an androgen deficiency. The deficiency in rats is caused by decreased plasma testosterone and dihydrotestosterone concentrations and unchanged plasma clearance of androgens and luteinizing hormone (LH) (Dickson and Buzik, 1993; Peterson *et al.*, 1993; Safe, 1994; Fielden *et al.*, 2001; Hsu *et al.*, 2003, 2007; Kuriyama and Chahoud, 2004; Oskam *et al.*, 2005; Foster *et al.*, 2010).

In most laboratory mammals, gestational exposure to TCDD produces a characteristic pattern of fetotoxic responses that consist of thymic hypoplasia, subcutaneous edema, decreased fetal growth, and prenatal mortality. In addition to these common fetotoxic effects, there are other effects of TCDD that are highly species specific, including cleft palate formation in the mouse and intestinal hemorrhage in the rat. In the mouse, hydronephrosis is the sensitive sign of prenatal toxicity, followed by cleft palate formation and atrophy of the thymus at higher doses and by subcutaneous edema and mortality at maternally toxic doses. In the rat, TCDD prenatal toxicity is characterized by intestinal hemorrhage, subcutaneous edema, decreased fetal growth, and mortality. Structural abnormalities occur in the rat only at relatively large doses. In the hamster fetus, hydronephrosis and renal congestion are the most sensitive effects, followed by subcutaneous edema and mortality. In the rabbit, an increased incidence of extra ribs and prenatal mortality is found, whereas in the guinea pig and rhesus monkey, prenatal mortality is seen (Birnbaum *et al.*, 1989; Couture *et al.*, 1990; Dickson and Buzik, 1993; Peterson *et al.*, 1993).

Based on LD<sub>50</sub> values, avian embryos are more sensitive to toxicity of TCDD and related compounds compared to mammals. Among bird species, most of the developmental toxicity research has been done on the chicken, which is considered to be the most sensitive avian species to TCDD-like chemicals. Injection of

TCDD or its approximate stereoisomers into fertilized chicken eggs causes a toxicity syndrome in the embryo characterized by pericardial and subcutaneous edema, liver lesions, inhibition of lymphoid development in the thymus and bursa of Fabricius, microphthalmia, beak deformities, cardiovascular malformations (cardiac dilation, thinner ventricle walls, and reduced responsiveness to chronotropic stimuli), and mortality. Clinical signs in turkey embryos include microphthalmia, beak deformities, and embryo mortality but not liver lesions, edema, or thymic hypoplasia, whereas ring-necked pheasant embryos experience only mortality. Thus, the clinical signs of toxicity of TCDD and its approximate stereoisomers are species dependent, with embryo mortality being the only common effect (Peterson *et al.*, 1993; Powell *et al.*, 1996; Kopf and Walker, 2009; Cohen-Barnhouse *et al.*, 2011).

Normal development of male reproductive organs and imprinting of typical adult sexual behavior patterns require that sufficient testosterone be secreted by the fetal and neonatal testes at critical times in early development before and soon after birth. Perinatal exposure of male rats to TCDD can produce both prenatal and postnatal androgenic deficiencies that are manifested as a decrease in anogenital distance; a delay in testis descent; decreased plasma concentrations of testosterone, 5 $\alpha$ -dihydrotestosterone, and LH; and a decrease in the weights of the seminal vesicles and the ventral prostate. Perinatal exposure of the rat to TCDD also results in decreased spermatogenesis as well as decreased testis and epididymis weights. In addition, demasculinization and feminization of sexual behavior has been reported (Golub *et al.*, 1991; Peterson *et al.*, 1993).

There have been several long-term bioassays for carcinogenicity of TCDD in several species, with all studies producing positive results. Studies of Sprague-Dawley rats indicated an increased incidence of hepatocellular hyperplastic nodules and hepatocellular carcinomas in female rats but not in male rats. Additional lesions noted were squamous cell carcinoma of the tongue and nasal turbinates/hard palate in both sexes. In addition to the liver, tongue, nasal turbinates, and hard palate, increased incidences of lung tumors were observed in females (Kociba *et al.*, 1978; Lucier *et al.*, 1993). In a study of Osborne-Mendel rats and B6C3F1 mice, TCDD induced malignant liver tumors in female rats and male and female mice. The incidence of thyroid gland tumors increased in male rats, whereas TCDD-induced neoplasms of the adrenal gland occurred in both male and female rats. Fibrosarcomas of the subcutaneous tissue occurred in both female rats and mice. Lymphomas and lung tumors were also observed in female mice (NTP, 1982; Lucier *et al.*, 1993). In the male Syrian golden hamster, exposure to TCDD resulted in squamous cell carcinomas of the skin in the facial region,

with some of the lesion metastasizing to the lung (Rao *et al.*, 1988; Lucier *et al.*, 1993). B6C3 and B6C mice of both sexes administered TCDD developed thymic lymphomas and hepatic neoplasms (Della Porta *et al.*, 1987; Lucier *et al.*, 1993).

The studies cited previously that are summarized by Lucier *et al.* (1993) indicate that TCDD is a multisite carcinogen in both sexes, and in several species it is a carcinogen in sites remote from the site of treatment and it increases cancer incidence at doses below the maximum tolerated dose. In two-stage models for liver and skin cancer, it is clear that TCDD is a potent promoting agent with weak or no initiating activity. The consensus is that TCDD is an example of a receptor-mediated carcinogenesis in that (1) interaction with the AhR appears to be a necessary early step; (2) TCDD modifies a number of receptor and hormone systems involved in cell growth and differentiation, such as epidermal growth factor receptor and the estrogen receptor; and (3) hormones exert a profound influence on the carcinogenic actions of TCDD. Although tumor promotion data are limited for PCDFs and coplanar PCBs, it appears that these chemicals are liver tumor promoters with potencies dependent on their binding affinity to the AhR (Lucier *et al.*, 1993; Schwarz and Appel, 2005).

## TREATMENT

The PBB incident in Michigan that resulted in the contamination and subsequent disposal of thousands of animals and millions of pounds of contaminated food products because of the long biological half-lives of these compounds prompted investigation of ways to enhance elimination of persistent PHAHs. Strategies reported in Fries (1985) included activated charcoal in rats and cows (Cook *et al.*, 1978; McConnell *et al.*, 1980); mineral oil in rats and monkeys (Kimbrough *et al.*, 1980; Rozman *et al.*, 1982); high fiber diets in rats (Kimbrough *et al.*, 1980); phenobarbital in cows (Cook *et al.*, 1978); and colestipol, mineral oil, propylene glycol, or petroleum jelly with or without restricted feeding in chickens (Polin *et al.*, 1985, 1989). In general, none of these elimination enhancement strategies proved to be effective despite the fact that they were employed for periods of 3–6 months (Fries, 1985). Other studies have examined different strategies to increase clearance of dioxins from animals. Rats fed clenbuterol-supplemented feed for 10 days after exposure to TCDD had 30% less fat than control rats and a 30% decrease in the body burden of TCDD. In other studies, rats and mice fed dietary fiber, chlorophyll, or an insoluble evacuation substance (chlorophyllin-chitosan)

had significantly increased excretion of PCDDs and PCDFs and reduced TEQ body burden (Huwe, 2002).

As suggested previously, once animals have been contaminated with the persistent PHAHs, there are currently no practical methods available to quickly reduce body burdens. Therefore, in a contamination incident, products are removed from the market and animals may have to be destroyed. A common strategy to reduce concentrations of contaminants in exposed animals is to provide the animals with uncontaminated feed and withhold products from the market until concentrations of the contaminant have decreased to an acceptable level. In the case of the persistent PCBs, PBBs, and PCDDs, long half-lives in animals require long withdrawal periods. Estimates of the half-lives of PCBs/PCDDs/PCDFs in milk range from 40 to 190 days. In beef cattle adipose tissue, half-lives are in the range of 100 to 200 days. The half-lives of PCDDs in adipose tissue and eggs of chickens range from 25 to 60 days. Depuration is the only way to reduce body burdens, but it may be uneconomical in many situations because of the length of time required (Huwe, 2002).

Currently, the best way to reduce PCB/PCDD/PCDF concentrations in livestock is to minimize exposure. In general, the substitution of plant meals for animal and fish meals may prove to be an effective strategy to lower contaminant intake in livestock and aquaculture (Huwe, 2002).

## CONCLUSIONS AND FUTURE DIRECTIONS

The PHAHs, which include PCBs, PBBs, PCDDs, and PCDFs, are environmentally persistent, lipophilic compounds that have a tendency to bioaccumulate and biomagnify at the higher levels of the food chain. Concentrations of these chemicals have been detected in remote areas of the world and in a variety of animal species, including humans. Although certain of these chemicals can pose a very serious threat to the health of animals and humans, exposure situations are generally such that risks of health effects are low. The most significant problem for those involved in producing a safe food supply is contamination of food products beginning at the animal. In addition, there are areas of the environment that are heavily contaminated by these chemicals because of past industrial activities. Animals and humans residing in or near contaminated locations are certainly at risk for serious health effects. In these situations, efforts must continue to eliminate or reduce exposure to these very persistent and toxic chemicals.

## Polycyclic aromatic hydrocarbons

Aramandla Ramesh, Anthony E. Archibong, Ashley C. Huderson, Deacquita L. Diggs, Jeremy N. Myers, Darryl B. Hood, Perumalla V. Rekhadevi and Mohammad S. Niaz

### INTRODUCTION

Polycyclic aromatic hydrocarbons (PAHs) constitute a large family of organic compounds with two or more fused aromatic rings. They are semivolatile, sparingly soluble in water, highly lipophilic, and high-molecular-weight compounds. PAHs are adsorbed on particles in the air, soil, water, and sediment. These compounds are not released into the environment as single compounds; instead, they often occur as mixtures. Some representative PAHs that are present in the environment are shown in Figure 63.1.

FIGURE 63.1 Representative PAH compounds encountered in the farm environment.

PAHs are formed mainly as a result of pyrolytic processes, especially the incomplete combustion of organic materials during industrial and other human-initiated activities, such as processing of coal and crude oil and coal-fired power generation. Other sources of PAH contamination of the environment and exposure to humans, wildlife, and farm animals include industrial and automobile emissions, hazardous waste sites, refuse burning, wildfires, arson, and warfare (Ramesh *et al.*, 2004; Hood *et al.*, 2009). Both food ingestion and inhalation represent the major routes of PAH exposure to humans and livestock. From a food safety perspective, the contamination of food products of animal origin (milk, butter, cheese, meat, etc.) by PAHs has received considerable attention because these products provide nourishment to humans. Humans are exposed to PAHs either directly or indirectly. The direct pathways for human exposures to PAHs include ingestion of soil (accidentally by children) or vegetables. Secondary or indirect pathways include those through which humans are exposed to PAHs via the consumption of products of livestock, which themselves ingest PAHs by grazing on contaminated pastures and accidental consumption of soil (Hartemann, 2004).

The increasing contamination of the farm environment by these toxicants has raised awareness concerning possible risks to livestock and ultimately to the consumer. However, compared to their aquatic counterparts, the toxicity of PAHs to farm animals has not been studied in detail. Given the severity of global environmental contamination by PAHs in diverse matrices such as air, water, soil, roughage, and sediment (Ramesh *et al.*, 2011) and their environmental persistence (a half-life of

<sup>a</sup>Agricultural soil refers to soil that is used for agricultural operations, such as soil for food production (raising crops), pasture land, and grassland.

100 days in soil; Jurjanz *et al.*, 2008), higher mammals, including farm animals, are at an increased risk of PAH exposure, accumulation, and the adverse health effects that may ensue. Unfortunately, to date, no efforts have been made to provide a compendium of information on PAH intake, behavior, and biological fate in farm animals. This chapter is an attempt to summarize the key research findings in this area, the data gaps, and scope for future studies.

## EXPOSURE OF FARM ANIMALS TO PAHS

As a consequence of rapid industrialization, PAHs are released into the environment on a large scale (Ramesh *et al.*, 2011). The contamination of pastures by PAHs occurs via atmospheric deposit (dry or wet deposition of particles onto leaf surfaces; Wild *et al.*, 1992) and root absorption (Su and Zhu, 2008) of these compounds. Pastures close to highways (vehicular traffic) and industries register greater concentrations of PAHs (Dan-Badjo *et al.*, 2007). In this context, high levels of PAHs occur in grass, with levels ranging from 25 mg/kg to 1 g/kg dry weight (wt) (Table 63.1). Cattle that graze on pastures near highways and airports have been reported to ingest

2 mg of PAHs/animal/day (Crépineau-Ducoulombier *et al.*, 2004).

Soil is another important route of exposure to PAHs during grazing. The concentrations of PAHs in exposed soils are estimated to be more than 70 mg or 10,000 mg/kg dry wt (Table 63.2). Soil that is rich in clay-humus material (high organic carbon content) sequesters PAHs, which are not amenable to hydrolysis and microbial degradation (Verstraete and Devliegher, 1996). If the average intake of soil is approximately 0.5 kg/animal/day (Fries, 1996), soil ingestion contributes approximately 50 mg of PAHs into each animal/day (Bryeselbout *et al.*, 2000). Therefore, soil, in addition to grass, is another matrix that contributes to substantial PAH intake.

In addition to pastures and soil, the farm environment as a whole has been reported to be contaminated with PAHs. Common sources of farm animal exposure to PAHs are feedstuffs, drinking water, barn dust, and manure. The concentrations of PAHs reported were 210 µg/kg, 2150 µg/kg, 543 µg/kg, and 52 ng/L for feedstuffs, dust, manure, and drinking water, respectively (Raszyk *et al.*, 1998). The outdoor and indoor air for livestock dwellings was contaminated by PAHs; the concentrations for pig and cow houses were 3 and 9 ng/m<sup>3</sup> and 4 and 6 ng/m<sup>3</sup>, respectively (Cigánek *et al.*, 2002; Cupr *et al.*, 2005). Based on PAH concentrations in farm, barn, and cattle houses, Cigánek *et al.* (2002) calculated that

**TABLE 63.3** Total PAH exposure in farm animals: comparison between pigs and cows

	Pigs	Cows
Feeds ( $\mu\text{g}/\text{day}$ )	256	14,156
Water ( $\mu\text{g}/\text{day}$ )	0.80	1.5
Inspired air ( $\mu\text{g}/\text{day}$ )	0.25	2.2
Sum of intake ( $\mu\text{g}/\text{day}$ )	257	14,160
Exposure ( $\mu\text{g}/\text{kg}/\text{day}$ )	2.6	35

Reproduced from Cigánek *et al.* (2002) with permission of the Czech Academy of Agricultural Sciences.

PAH exposure is 20 times higher in cows than in pigs (Table 63.3).

Livestock may also be exposed inadvertently to accidental release of PAHs near oil and natural gas exploration and production sites that emanate these contaminants along with petroleum hydrocarbons (Pattanayek and DeShields, 2004). Accidental spillage of coal ash from coal-fired electric power plants and the atmospheric transport of coal ash plumes (Hood *et al.*, 2011) to farms in the catchment areas constitute another source of exposure for farm animals to PAHs through inhalation and ingestion. The absorption of PAHs through dermal contact in livestock is considered negligible compared to ingestion of fodder and soil (Jurjanz *et al.*, 2008).

### UPTAKE, DISPOSITION, BIOACCESSIBILITY, AND BIOAVAILABILITY OF PAHS IN FARM ANIMALS

As mentioned previously, feed is the major source of PAHs for livestock – that is, up to 99% (Cigánek *et al.*, 2002). The dietary habits determine the levels of PAH intake. Domesticated dairy and meat animals are usually raised in confinement (indoors) or on pastures. Whereas animals such as pigs and rabbits are housed indoor, cows, goats, sheep, and horses graze on farmlands (that could be polluted) with occasional supplementation with feed concentrates. Bioaccessibility and bioavailability studies are conducted by various research groups to demonstrate the transfer of PAHs from feed matrices to the digestive tract, milk, and eventually the general circulation. When PAH intake from complex matrices such as soil by rats and farm animals is involved, the terms bioaccessibility and bioavailability have been used interchangeably in the literature, causing confusion to readers. For the sake of clarity, both terms are defined here. Whereas bioaccessibility refers to the fraction of toxicant

intake that is available for absorption in the gastrointestinal tract, bioavailability refers to the fraction of administered dose of a toxicant that reaches the systemic circulation (blood compartment) from the gastrointestinal tract (Paustenbach, 2000).

### Transfer of PAHs in cows

As part of larger studies that are directed at unraveling the mechanisms that govern the chemical behavior and fate of PAHs, Costera *et al.* (2010) conducted studies to access the release of PAHs from grass in the digestive tract of ruminants. Three cows fitted with a rumen fistula were used to introduce six nylon bags containing  $4\mu\text{g}$  PAHs/g dry wt of grass containing phenanthrene (Phe), pyrene (Pyr), and benzo(*a*) pyrene (BaP) into the rumen of each animal. The bags were incubated for time periods of 1, 3, 6, 12, 24, and 48 h. The disappearance rates for the PAHs administered were greater than 90, 81, and 80% for Phe, Pyr, and BaP, respectively, whereas for grass it was 20–60%. These studies revealed a rapid disappearance rate for PAHs in ruminants, whereas the feed matrix (grass, which served as a carrier for PAHs) had no effect on the bioavailability of PAHs.

Among farm animals, cows ingest a greater amount of PAHs (approximately  $2\text{mg}/\text{day}$ ) via roughage (Crèpineau-Ducoulombier *et al.*, 2004) by grazing on pastures close to highways and airports, where the PAH residue levels in soil were reported to exceed those in grass (Crèpineau-Ducoulombier and Rychen, 2003; Dan-Badjo *et al.*, 2007). Residual concentrations of PAHs up to  $100\text{--}200\mu\text{g}$  PAH/g of soil have been reported (Ramesh *et al.*, 2011), and if these values are extrapolated to consumption of soil by cattle, PAH intake of  $50\text{mg}/\text{day}$  can be expected. The mobilization of PAHs in soil during digestion (bioaccessibility) may play an important role in the disposition of PAHs in farm animals. To study PAH bioaccessibility in ruminants, Jurjanz and Rychen (2008) supplemented pasture soil with 5.4, 6.8, and  $8.4\text{mg}/\text{kg}$  of Phe, Pyr, and BaP, respectively. These PAHs were exposed to conditions that simulated the digestive compartments of the rumen, abomasums, and intestines. For all three PAH compounds studied, the bioaccessibility was more relevant for the rumen compartment than for the abomasum and intestine. Overall, Phe bioaccessibility was found to be higher compared to that of Pyr or BaP.

The aforementioned study demonstrated that soil-bound PAH parent compounds are bioaccessible in the ruminant digestive tract. This observation calls into question the possible transfer of these bioaccessible PAHs from the gastrointestinal tract to milk; if such a transfer occurs, would it be in the form of parent compound or metabolites? To investigate this question,

Lutz *et al.* (2006) administered soil fortified with fluorene (Flu; 104 µg/g dry wt of soil), Phe (82 µg/g), Pyr (78 µg/g), and BaP (33 µg/g) to dairy cows via rumen fistulae for 28 days. Whereas Phe, Flu, and Pyr have been found to be extensively metabolized and transferred to milk (as recorded by their metabolite concentrations in milk), BaP metabolites were not found to be secreted into milk. Mammary epithelium plays an important role in the transfer of PAH from food to milk. Using a bovine mammary cell line, Cavret *et al.* (2005a) demonstrated transepithelial permeability of <sup>14</sup>C-labeled BaP, Pyr, and Phe. These studies revealed that Phe and Pyr were able to cross mammary cell layers, whereas BaP was not. The differences in transfer rates support the contention that the lipophilicity and molecular weight of PAH govern their transport across the mammary epithelium. These findings demonstrate that subsequent to biotransformation, the unchanged parent compound (if any) and metabolites are likely to be distributed to target tissues such as liver, intestine, adipose, and muscle and reproductive tissues, as shown for cattle (Cigánek and Neca, 2006) and sheep (Rhind *et al.*, 2011), or excreted through urine, as demonstrated for goats (Grova *et al.*, 2002).

Additional experiments by Cavret *et al.* (2003) employed Caco-2 (human colon carcinoma) cells to measure the transepithelial intestinal permeability for Phe and BaP. After a 6-h exposure, the absorption levels of Phe and BaP were 9.5 and 5.2%, respectively. Cavret *et al.* (2005b) also studied the uptake and transport of <sup>14</sup>C-labeled BaP, Pyr, and Phe in Caco-2 cells. Although all three PAHs were able to cross intestinal layers, Pyr and Phe, which have a lower lipophilicity, were found to rapidly cross the intestinal barrier compared to BaP, which is relatively more lipophilic. As a result, extensive metabolism of BaP occurs in the intestine, and accumulation of metabolites takes place in target tissues and they become bioavailable. In other words, the faster a PAH crosses the intestinal barrier, the less metabolized it will be in the intestine (Cavret *et al.*, 2004). Cavret and Feidt (2005) conducted studies on the transepithelial passage of BaP, Pyr, and Phe in Caco-2 cells. The intestinal transfers of BaP, Pyr, and Phe, respectively, were found to be 26, 4, and 2 times lower with CYP (1A1, 1B1, and 3A4) inhibitors. These studies provide additional evidence that intestinal metabolism of PAHs play a pivotal role in their bioavailability in higher mammals.

### Transfer of PAHs in pigs

To study whether PAH absorption in intestine occurs in concert with fat absorption, Laurent *et al.* (2001) administered pigs with [<sup>14</sup>C] Phe and [<sup>14</sup>C] BaP through milk and assayed their concentrations in blood. Both these compounds reached peak levels in blood within 5 or 6 h

after ingestion. The difference in molecular weights (Phe 178 vs. BaP 252) and water solubilities (Phe 1.2 mg/L vs. BaP 3.8 µg/L) notwithstanding, the absorption rates for these two compounds were found to be similar to that observed for fat absorption (Dubois *et al.*, 1996). Based on these findings, it appears that (1) transport of PAHs from milk to blood occurs through lipid phase rather than aqueous phase, and (2) the more lipophilic members of PAHs are poorly absorbed by the intestine from feed materials (Hoogenboom, 2005).

### Transfer of PAHs in sheep and goats

The study conducted by West and Horton (1976) was the first to demonstrate that lactational transfer of PAHs occurs in sheep. In this study, radiolabeled 3-methylcholanthrene and BaP were orally administered to sheep. No parent compound was present in milk, but the hydroxylated products were present. These compounds were metabolized from 33 to 55% (of the parent compound) within 24 h after administration. For both these chemicals, the proportion of water-soluble material (presumably metabolites) increased with time.

Grova *et al.* (2002, 2005) studied the excretion of PAHs in milk, urine, and feces of goats subsequent to a single oral administration of 5 µg/kg <sup>14</sup>C-Phe, <sup>14</sup>C-Pyr, and <sup>14</sup>C-BaP. The lactational transfer factors (percentage parent dose) were found to be 1.5, 1.9, and 2%, respectively, for the previously mentioned compounds. The urinary excretion rates for Phe, Pyr, and BaP were 40, 11, and 6%, respectively, whereas the fecal excretion rates for these compounds were 22, 20, and 88%, respectively. Perhaps the configuration of BaP (five benzene rings) compared to those of Phe (three benzene rings) and Pyr (four benzene rings) may have been responsible for the differential processing of these chemicals by goats. In a follow-up study conducted by this research group (Grova *et al.*, 2006), 20 µg PAHs/kg body wt was administered to goats for 28 days. Parent compounds and their hydroxylated metabolites were detected for most of the PAHs in milk except for BaP. Lapole *et al.* (2007) also documented similar behavior and fate for hydroxylated metabolites of these chemicals.

Similar to the studies conducted in cows, Costera *et al.* (2009) studied the bioavailability of Phe, Pyr, and BaP administered to goats through oil (castor oil polyether), hay, or soil. Because the weights of the animals were not provided, it is difficult to compute the exact doses of the chemicals administered. However, the amount of PAHs ingested by the goats varied from 17 to 50 mg. The authors found an increased excretion of PAHs through urine compared to milk. Among the three matrices used, the absorption rates (as reflected by the urine and milk excretion rates) were higher for hydroxylated

metabolites of Phe and Pyr when oil was used as a support matrix compared to hay and soil. Interestingly, the differences between soil and hay in the transfer kinetics of PAHs were negligible.

In a subsequent bioavailability study in goats, Ounnas *et al.* (2009) used three doses of the previously mentioned PAHs using soil and sunflower oil as matrices. The relative bioavailability of Phe and Pyr was found to be enhanced when oil was used as a vehicle instead of soil. Soil was reported to sequester PAHs (Bogan and Sullivan, 2003), thereby limiting the PAH fraction available for absorption. On the basis of PAH excretion rates through urine and milk, Ounnas *et al.* (2009) computed absorption rates of more than 30% for PAH parent compounds and metabolites in ruminants. These findings therefore indicate the need for factoring in soil ingestion parameter when assessing the PAH exposure risk to grazing ruminants, recognizing that cattle consume approximately 0.5 kg/animal/day (Fries, 1996).

## BIOTRANSFORMATION OF PAHS IN FARM ANIMALS

Absorbed PAHs into farm animals undergo a series of enzymatic reactions referred to as "biotransformation." Consequently, the toxicants become less lipophilic and more hydrophilic (polar) in the body to be excreted eventually. Drug-metabolizing enzymes possess different substrate specificities, and their expression levels are affected by exposure to PAHs as well as by physiological factors (Graham and Lake, 2008). Although biotransformation serves as a detoxification strategy, biotransformation enzymes generate stable metabolic products that are highly reactive and severalfold more toxic than the parent compounds. Some of the reactive intermediates (metabolites with a short half-life) exert local toxicity in the target tissues where they are generated. On the other hand, other intermediates (metabolites with a long half-life) may be produced in liver, released into the general circulation, and become bioavailable to affect distant tissues (Connelly and Bridges, 1980).

Although most PAHs have been suspected of causing toxicity, and a few of them of causing cancer, more than 100 types of PAHs are known to exist in nature. This necessitated using a surrogate PAH compound to gain comprehensive information on the mechanisms involved in the development of toxicity/cancer by these chemicals. BaP is well suited for this role because this chemical is considered a prototypical PAH compound, being the most extensively characterized and studied in terms of its toxicity. Here, we provide a snapshot

of metabolic biotransformation of BaP, which is relevant in understanding the causal factors involved in PAH toxicity.

Initial oxidation of BaP is catalyzed by the CYP450 family of enzymes (CYP1A1, CYP1A2, and CYP1B1), yielding arene oxides (9-OH-BaP, 7-OH-BaP, 6-OH-BaP, 3-OH-BaP, and 1-OH-BaP). These arene oxides rearrange to phenols or undergo hydration that is catalyzed by epoxide hydrolase (EH) with the resultant generation of BaP-9,10-diol, BaP-7,8-diol, and BaP-4,5-diol (Shimada and Guengerich, 2006). The previously mentioned metabolites (epoxides, hydroxy metabolites, and dihydrodiols) represent phase I metabolites of BaP. Phase I metabolism introduces more polar chemical groups such as hydroxy metabolites into the molecule. As a result, the molecule becomes more electrophilic, leading to increased reactivity. A good example of electrophilic metabolite formation is BaP 7,8-oxide, which is inactivated by microsomal epoxide hydrolase to 7,8-dihydrodiol. The 7,8-dihydrodiol serves as a substrate for a second monooxygenation step, which introduces a further epoxide moiety leading to the formation of a dihydrodiol bay region epoxide, termed the BaP 7,8-diol 9,10-epoxide (BPDE; Oesch *et al.*, 1990). Some of the precursors of BaP reactive metabolites, such as the 3-hydroxy BaP and 7,8-diol, are lipophilic, resulting in an increase in uptake by plasma lipoproteins (Shu and Nichols, 1981), transported through blood, and undergo cellular internalization (Busbee *et al.*, 1990). The phase I metabolites are conjugated with glutathione, sulfate, or glucuronic acid to form phase II metabolites. The phase II metabolites (4,5-diol glucuronide; 9,10-diol glucuronide; 3(OH) glucuronide; 3(OH) sulfate; 9(OH) sulfate; 7,8-diol GSH; and 9,10-diol GSH) are more hydrophilic and hence amenable for elimination through excretion (Ramesh *et al.*, 2011). Phase II metabolism is considered a detoxification reaction. However, activation of some of the phase II metabolites cannot be ruled out because of alterations in electrophilicity as BaP undergoes simultaneous and stereoselective metabolic transformations, like many chemical carcinogens (Oesch *et al.*, 1990).

Of the drug-metabolizing enzymes that contribute to differential susceptibilities to the adverse effects of BaP, the CYP1A1 is not constitutively expressed and CYP1A2 is mostly hepatic (Guengerich, 1997). Therefore, the biotransformation of BaP in extrahepatic tissues such as testis or ovary may have been the result of CYP1B1, which is constitutively expressed in these tissues (Otto *et al.*, 1992). The biotransformation enzymes that metabolize PAHs such as CYP1A1, CYP1A2, CYP1B1, UDP glucuronyltransferase, and glutathione S-transferase have been reported to be constitutively expressed in livers of goats, sheep, and pigs (Kaddouri *et al.*, 1990; Eltom and Schwark, 1999; Kojima *et al.*, 2008).

Our understanding of potential health risks of PAHs to livestock is based on laboratory rodent studies. A majority of these studies have been conducted with the sole aim of understanding the risks to human health, especially cancer. The relevance of these data to livestock health is a matter of debate and presents a major lacuna in regard to veterinary PAH toxicology. Collection of robust and statistically reliable data from target tissues requires terminal surgeries on multiple days after exposure. Although routinely followed in laboratory animal models, this strategy of sacrificing a considerable number of farm or domesticated animals per species raises ethical questions from an animal welfare standpoint. This is a major factor that limits our ability to pursue PAH disposition studies in livestock/domesticated animals. To overcome this limitation, our research group has used microsomes isolated from liver, testis, and ovary tissues of farm animals collected from abattoirs to study the metabolism of PAHs such as BaP and fluoranthene (Harris *et al.*, 2009). Microsomes are the subcellular organelles that harbor drug-metabolizing enzymes. These organelles have long been used as one of the *in vitro* models for studying the metabolism of toxic chemicals.

Microsomes were isolated from the liver and reproductive tissues of rat, mouse, boar, bull, cow, goat, and sheep and incubated with 5  $\mu$ M BaP. Post-incubation, samples were extracted with ethyl acetate and analyzed for BaP/metabolites by reverse-phase high-performance liquid chromatography with fluorescence detection (Walker *et al.*, 2006; Harris *et al.*, 2009). Our results revealed a great variation among species to metabolize BaP. Compared to rodents (rat and mouse), the BaP metabolite concentrations produced by bull/cow, goat, sheep, and pig testicular or ovarian or hepatic microsomes were higher ( $p < 0.05$ ). Hepatic microsomes produced the greatest quantities of metabolites relative to that of testicular and ovarian microsomes in all the species studied ( $p < 0.05$ ). This observation is not surprising inasmuch as the liver functions as the main detoxifying organ in mammalian species. Because liver is the principal detoxifying organ of BaP, it contributes metabolites through circulation to extrahepatic tissues under *in vivo* conditions. The continuous delivery of metabolites from the liver to the testis or ovary enhances the levels of reactive metabolites in reproductive tissues, which will ultimately have implications on the functioning of these organs.

The BaP metabolites identified in testis, ovary, and liver were BaP 9,10-diol, BaP 4,5-diol, BaP 7,8-diol, and 3-hydroxy and 9-hydroxy BaP. The rodent testicular microsomes produced a considerably higher proportion ( $p < 0.05$ ) of BaP 4,5-diol and 7,8-diol than did the other animal species (ewe, sow, and cow). However, hepatic microsomes from the latter farm animal group

converted a greater proportion ( $p < 0.05$ ) of BaP to 3- and 9-hydroxy BaP. There were no remarkable differences between hepatic and reproductive tissue microsomes of livestock in the BaP metabolite types formed. The hydroxy metabolites are believed to be a part of the detoxification pathway. However, it has been shown that 3-OH-BaP (Moorthy *et al.*, 2003) and 9-OH-BaP (Moorthy and Randerath, 1996), the products of detoxification, also react with DNA to form adducts in target tissues. Consequently, higher mammals, due to their high metabolizing capabilities, are expected to generate high concentrations of these two metabolites, whose accumulation in target tissues is relevant from a toxicological standpoint. Darwish *et al.* (2010) reported mutagenic activity of CYP1A1 in cattle, deer, and horses using BaP as a test compound. Their research showed that the ability to metabolize BaP is highest in the horse, followed by cattle and deer. These authors also demonstrated a similar trend of activities of UDP-glucuronosyltransferase in the previously mentioned species, whereas glutathione transferase activity was highest in horses, followed by deer and cattle.

### Effect of sexual maturity on BaP metabolism

To delineate the influence of sexual maturity on BaP metabolism, ovaries from commercial crossbred prepubertal gilts (7 or 8 months old; ovaries with follicles and no corpora lutea) and those of postpubertal gilts (ovaries with corpora lutea of various stages of development or corpora albicans) were used (Harris *et al.*, 2009). Inasmuch as it has been established that the metabolism of PAHs in mammalian ovary is hormonally regulated (Bengtsson *et al.*, 1987), our research group conducted a study designed to measure the BaP metabolite concentrations produced by microsomes isolated from prepubertal and sexually mature gilts and confirmed that BaP metabolism was indeed influenced by sexual maturity (Harris *et al.*, 2009). Microsomes isolated from the ovaries of sexually mature gilts that were at the mid-luteal and follicular phase of the estrous cycle metabolized BaP rapidly compared to ovarian microsomes isolated from prepubertal gilts (Table 63.4). The high concentrations of metabolites in luteal phase are probably due to a high constitutive expression of CYP in the corpora lutea (CL). Our findings are in agreement with those of Eliasson *et al.* (1997), who reported that the metabolism of dimethylbenz(a)anthracene (DMBA; a PAH compound) was highest in the CL of pigs compared to preovulatory follicles. Furthermore, the higher concentrations of BaP metabolites in the organic fraction (less polar) in the CL could be secondary to the higher lipid content of the CL.

**TABLE 63.4** Benzo(a)pyrene metabolite concentrations generated by microsomes from various stages of estrous cycle in pig

Ovarian status	Description	BaP metabolite concentrations (pmol/min/mg protein)
Prepubertal (n = 6)	Minimal estrogen stimulation of the uterus	0.10 ± 0.0001***
Prepubertal (n = 4)	Some uterine stimulation	0.12 ± 0.01**
Postpubertal (n = 2)	Follicular to late follicular phases, 14–15 CA, many 4- or 5-mm follicles	0.17 ± 0.02*
Postpubertal (n = 5)	Mid-luteal, 11–17 CL	0.22 ± 0.02

\* $p < 0.01$ ; prepubertal (some estrogen stimulation) versus postpubertal (follicular); \*\* $p < 0.001$ ; prepubertal (some estrogen stimulation) versus postpubertal (follicular and mid-luteal); \*\*\* $p < 0.0001$ ; prepubertal (minimal estrogen stimulation) versus postpubertal (follicular and mid-luteal).

CA, corpora albicans; CL, corpus luteum.

## HEALTH EFFECTS OF PAHS IN FARM ANIMALS

There is a mistaken perception that environmental contaminants such as PAHs in farm animals are completely metabolized and excreted. The argument in support of this assumption arises from the observation that environmental levels of PAHs are low, that these compounds are extensively degraded in the gastrointestinal tract, and that the residual levels of these compounds remaining after metabolism are too low to exert any toxic effect (Rhind, 2005). On the contrary, despite the decline in the environmental release of PAHs, local inputs and different sources of pollution in the tropical belt and long-range atmospheric transport of PAHs from point source areas have led to a buildup of these compounds even in pristine areas (Ramesh *et al.*, 2011). Another related argument is that although short-term high-level exposure of farm animals to PAHs can be processed through metabolism and/or excretion of parent compounds, continuous or long-term exposure to low levels of PAHs results in bioaccumulation of persistent PAHs in target tissues (Bechtel *et al.*, 2009), and the sustained delivery of reactive metabolites from liver to vulnerable tissues/organs is sufficient to cause toxicity.

The farm environment is considerably contaminated with PAHs from feed ingredients such as dried grass and corn silage, which also registered high levels of PAHs. Using the feed PAH residue data, the calculated

intake of PAHs by cows was found to be 65–1000 times higher than the calculated intake by humans (Bulder *et al.*, 2006), which indicates a potential risk for cattle health. According to CCME (2010), the possible effects of various PAHs on exposed livestock include, but are not limited to, growth inhibition, endocrine disruption, reproductive impairment, and liver and kidney damage.

In estrogen receptor binding assays and reporter gene assays, BaP/metabolites were reported to be estrogen (Arcaro *et al.*, 1999) and androgen (Vinggard *et al.*, 2000) antagonists. Furthermore, studies conducted in our laboratory revealed that subacute exposure to BaP resulted in anti-estrogenic and anti-androgenic activities (Inyang *et al.*, 2003; Ramesh and Archibong *et al.*, 2011) that are driven by BaP metabolism. Interestingly, the microsomal CYP family of enzymes that generate these metabolites in the liver and extrahepatic tissues such as testis are also involved in steroid hormone metabolism (Jefcoate *et al.*, 2000). Upon prolonged exposure to BaP, sequestration of this chemical in high-density lipoproteins, which are essential for steroid hormone biosynthesis in the reproductive tissues, cannot be ruled out (Polyakov *et al.*, 1996). This can lead to reduced testosterone synthesis and release by the Leydig cells, with adverse implications on testosterone-regulated spermatogenesis in male farm animals.

## Reproductive and developmental toxicity

Livestock are exposed to a myriad of toxins (poisonous plants and mycotoxins) and toxicants (environmental pollutants such as pesticides, metals, PAHs, PCBs, and dioxins), both in the farm environment and in controlled settings (Archibong and Abdelgadir, 2000). In the face of threat from these chemicals and biotoxins, maintaining optimum reproductive efficiency of livestock is a constant challenge as the economic returns are affected. From this perspective, it is important to know how PAHs perturb the reproductive efficiency of farm animals/livestock. To date, no studies have been conducted on PAH-induced perturbations in fertility of farm animals. As mentioned previously, most of the studies on the endocrine disruptive actions of PAHs have been conducted using rodent models exposed to single PAH compounds for short durations, a treatise of which has been published by our research group (Hood *et al.*, 2011; Ramesh and Archibong, 2011). The laboratory rodent models differ from the bovine, ovine, or porcine animals in dietary habits, metabolism, and physiology. Nonetheless, PAHs including BaP have steric resemblance to steroid molecules (Santodonato, 1997) and have been demonstrated to have both estrogenic and anti-estrogenic activities (Chaloupka *et al.*, 1992; Charles *et al.*, 2000). Studies conducted by our research team using a rat model have

revealed that BaP affects the serum concentrations of progesterone, androgens, estrogens, prolactin, and, indirectly, luteinizing hormone (Ramesh and Archibong, 2011). Therefore, PAHs can influence reproductive efficiency in exposed farm animals in a similar manner as recorded for lower mammals, albeit to a different extent.

The adverse effect of BaP on male fertility indices was confirmed when adult male rats were exposed to BaP via inhalation. Specifically, a subacute exposure (10 days) of adult F-344 male rats via inhalation to BaP (75 µg BaP/m<sup>3</sup>) caused a significant reduction in stored sperm motility and circulating testosterone concentrations (Inyang *et al.*, 2003). Furthermore, a subchronic exposure of adult F-344 male rats to this PAH significantly reduced testis weight, spermatid numbers, stored sperm density, progressive motility, spermatozoa with normal morphology, intratesticular testosterone concentrations, and circulating testosterone (Ramesh and Archibong, 2011). The fertility indices described previously and the functioning of the male reproductive system in general are regulated by testosterone, whose synthesis and release by the testis is repressed by BaP. The mechanism by which BaP perturbs testosterone synthesis and release is linked to ROS-induced oxidative aging (Senft *et al.*, 2002) of the Leydig cells by damaging critical components of the steroidogenic pathway in the Leydig cells (Peltola *et al.*, 1996).

Sex differences in the constitutive expression of hepatic CYP1A1 and 1A2 in Meishan pigs have been reported by Kojima *et al.* (2008). These findings suggest androgen-dependent down-regulation of genes coding for the previously mentioned biotransformation enzymes. Further studies by this research group demonstrated that physiological concentrations of serum testosterone regulate the constitutive gene expression of CYP1A1 and 1A2 in Meishan and Landrace pigs (Kojima *et al.*, 2010). Hence, the metabolism of PAHs by the CYP family of enzymes in steroidogenic and reproductive tissues of farm animals is detrimental to hormonally regulated developmental events such as male and female gamete production, their ability to interact, and the development of generated embryo to a viable young.

The ovotoxicity of BaP has been studied in rodents. DMBA, 3-methylcholanthrene (3-MC), and BaP were reported to destroy oocytes in ovarian follicles of rats and mice (Borman *et al.*, 2000). In general, PAH parent compounds are not directly ovotoxic. They require metabolic biotransformation to reactive metabolites. Ovarian enzymes involved in the biotransformation of PAHs (CYP1B1, AHH, and epoxide hydrolase) have been identified in mice, rats, and primates (Hoyer, 2004). Consequently, oocyte destruction by PAHs may be preceded by the distribution of the parent compound to the ovary, where PAH biotransformation enzymes metabolize the compounds to reactive intermediates (Harris *et al.*, 2009). These reactive intermediates are capable of

covalent binding to macromolecules such as DNA, RNA, and proteins (Ramesh *et al.*, 2010).

Polycyclic hydrocarbons have toxic effects on mammalian fetal development. Pregnant mice or rats treated during early or middle gestation with BaP, 3-MC, or DMBA show significant increases in embryo lethality and resorption; surviving fetuses have a greater incidence of malformation (Galloway *et al.*, 1980). Our findings in F-344 rats indicate that transplacental exposure to BaP affects fetal survival, intrauterine growth, and pregnancy-related hormones (Ramesh and Archibong, 2011). Fowler *et al.* (2008) showed that low doses of environmental chemicals present in sewage sludge significantly perturb fetal ovarian development in sheep. A marked decline in prolactin, estradiol concentrations, and follicle numbers was observed. Also, an alteration in balance between pro- and anti-apoptotic proteins and a reduced level of superoxide dismutase expression were noted. These findings emphasize that long-term exposure to low doses of complex environmental mixtures such as sewage sludge (of which PAHs are a component; Smith *et al.*, 2001) may result in impaired fertility of livestock.

Reports indicate that PAHs interact with the endoplasmic reticulum (ER)  $\alpha$  and  $\beta$  signaling pathways in a variety of test systems and subsequently interfere with estrogen signaling in important reproductive processes (Arcaro *et al.*, 1999; Fertuck *et al.*, 2001). Exposure to PAHs has been shown to suppress estrogen response element-controlled gene expression and increase estradiol metabolism and down-regulation of ER  $\alpha$  levels (Safe, 2001). The action of PAHs on the steroidogenic activities in the ovary is not limited to inhibition of estrogen production. It also enhances the clearance of circulating estrogens. Induction of CYP1A1 in porcine ovarian granulosa cells by 3-MC indicates that PAHs may decrease plasma estrogens by enhancing their clearance through CYP1A1 induction (Leighton *et al.*, 1995). The P450 isoforms CYP1A1, CYP1A2, and CYP1B1 are involved in PAH biotransformation (Ramesh *et al.*, 2004). Induction of P450s by PAHs may also lead to increased metabolism of estrogens because the same P450 isoforms are involved in estrogen catabolism. For example, estrogens are metabolized by CYP1A1, CYP1B1, CYP3A4, and CYP3A7 to catechol estrogens. The catechols undergo metabolic redox cycling to generate free radicals such as reactive quinone/semiquinone intermediates (Jefcoate *et al.*, 2000). These metabolic intermediates initiate toxicity. Therefore, it can be concluded that the repression of estrogen biosynthesis and enhanced metabolism of E<sub>2</sub> by BaP can result in the reduction of the circulating concentrations of this ovarian steroid below physiological threshold essential for maintaining reproductive health.

Because PAHs are lipophilic, they reside in fat depots and tissue lipids. In addition to mesenteric, pericardial, and perirenal fat, most farm animals deposit

subcutaneous fat in loin, ribs, tail head, brisket (lower part of the chest), flank, around ovaries and lipid components of the gonads, and in udder (mammary gland). These sites are potential storage depots for PAHs. In a continuous exposure scenario, the more lipophilic and high-molecular-weight PAHs tend to bioaccumulate to a greater extent in lipid-rich tissues and lipid depots. These persistent isomers are not easily available for metabolism. Even if some of these PAH parent compounds are partially metabolized, the reactive metabolites generated are released into the bloodstream. Busbee *et al.* (1990) demonstrated that gastric instillation of BaP in sheep was transported to vascular circulation in association with lipoproteins, and this absorbed fraction was internalized in vulnerable tissues. This situation ensures insults at the cellular level, culminating in organ

dysfunction. In addition, conditions such as malnutrition and aging mobilize fat reserves in the body. As a result of fat catabolism, the previously sequestered PAHs are released directly into the bloodstream, thus bypassing the hepatic detoxification. Compared to lower mammals, livestock such as cattle, sheep, goats, pigs, and camels enjoy a long life span. Hence, the consequences of long-term low-level exposures to PAHs via feed, soil, and inhalation could be deleterious not only to the farm animals per se but also for the survival and propagation of the previously mentioned species. The metabolic fate of PAHs in a pregnant cow and suckling calf are shown in Figure 63.2.

There is little information available to establish an exposure–effect relationship pertaining to PAH exposure, incidence of pathological abnormalities, and

**FIGURE 63.2** Exposure pathways, disposition, and metabolic fate of PAHs in farm animals. Upon intake of PAHs by livestock through feed, these compounds are metabolized in the intestine, liver, and reproductive tissues. The metabolites are carried to other organs and tissues of the adult animals through circulation and to pre- and postnatal animals through placenta and milk, respectively. Some of the high-molecular-weight PAHs and/or their metabolites are sequestered in fat depots in various parts of the body. Catabolism of these lipid pools releases the PAH parent compounds and/or their metabolites into circulation, contributing to total body burden of these toxicants. Because some of these metabolites are estrogenic and/or anti-estrogenic, they interfere with hormonally regulated events such as sexual maturity, reproduction, and embryo development.

incidence of cancer in animals of agricultural and veterinary interest. However, the incidence of gastric and mammary cancers in wildlife (Martineau *et al.*, 2002) and humans who inhabit areas that are in proximity to aluminum smelters (Bye *et al.*, 1998) does not rule out the possible involvement of PAHs in causing such effects in farm animals too. Given the ability of PAHs to suppress the immune system (Davila *et al.*, 1996), a survey was conducted by Bechtel *et al.* (2009) to determine whether the immunity of cattle was compromised due to PAH exposure. Blood samples were collected from yearling cattle on farms located near oil and natural gas facilities. These animals were also exposed to particle-bound PAHs released from flares. The B lymphocytes, populations of T lymphocyte subtypes, and antigen-specific serum antibodies were enumerated along with particulate matter that was less than 1  $\mu\text{m}$  in diameter. The lack of consistency in results indicates no significant association between exposures to PAH and immune system functions (Bechtel *et al.*, 2009). Whether the cattle were exposed to PAH concentrations that were high and stable enough to cause immunological adverse effects is open for speculation. Perhaps PAHs may not be sufficiently strong immunosuppressants in livestock to cause cancerous tumors but may exert toxicity to other organ systems.

## TREATMENT

Specific antagonists or antidotes to counter PAH-induced toxicity in livestock are not available. Skin contamination may be reduced by thorough scrubbing with detergents and water. For fur-bearing animals such as sheep, shearing is required before washing. Personnel involved in cleaning animals that live near oil and natural gas facilities (rich sources of PAHs) must wear personal protective equipment such as safety glasses, gloves, masks, and aprons to prevent self-contamination.

Although oral administration of charcoal is a decontamination strategy that may be used for other toxicants, it may not be a preferable one given the fact that the palatability of charcoal is very poor. Also, charcoal may contain residual levels of PAHs that may exacerbate toxicity. Rationing of feed intake is another time-tested strategy used for decontaminating the lipophilic toxicants. The idea behind this strategy is that a reduction in body fat may release the PAHs from the fat depots. Although this strategy may yield results for male and nonpregnant female livestock, it may not be practical for lactating animals because they eliminate the PAHs through milk secretion. Furthermore, rationing of feed to dams may impact the well-being of calves because of malnutrition.

If the animals are raised for milk or meat production, farmers may be reluctant to adopt this strategy. Another effective strategy is to feed the animals some herbage or silage or hay that is rich in phytochemicals or phytoestrogens because most of these phytochemicals have high detoxification potential and chemopreventive properties. Legumes, peanuts, broccoli, and soy may be supplemented in feed. The efficacy of these measures can be tested by monitoring the levels of PAHs in blood, urine, and manure (if possible) subsequent to administration of these bioactive feed supplements. These remedial measures coupled with a proactive background environmental monitoring (checking for PAH residue levels in air, soil, feed, etc.) for PAH contamination could reduce exposure to PAHs.

## CONCLUSION AND FUTURE DIRECTIONS

Despite the attention PAHs have commanded during the past several decades in view of their environmental prevalence and contamination of animal-derived products, there is inadequate information regarding the toxicity of these compounds to livestock. The uptake, accumulation, and persistence of PAHs in livestock tissues and their transfer to food products can have an impact on human health.

The internal dose determines the chemical behavior and manifestation of symptoms of toxicity in livestock. In other words, the net absorption is the critical factor that controls the internal dose. Some ingredients in livestock feed contain fat, and to increase the yield of meat and for greater economic returns, farmers tend to use fatteners and feed supplements for feedlots. Because PAHs are absorbed concomitantly with fat, consumption of PAH-contaminated fatteners may result in carryover of PAHs from feed ingredients to edible products (milk, meat, and eggs). However, studies thus far have focused on bioaccessibility of PAHs given through hay, soil, or milk but not commercial feed and additives or supplements. Thus, more work needs to be done on the absorption of PAHs taken through diverse matrices for modeling the chemical fate of ingested PAHs with the ultimate purpose of establishing any species specificity. The stability of metabolic products of PAHs in edible products requires attention. Although the metabolites of more lipophilic PAHs may not undergo carryover (to milk) compared to their less lipophilic counterparts, the stability of these PAH metabolites in food products derived from animals that have been subjected to frequent episodes of PAH exposure is open for speculation. Also, the interactions between PAHs and metals, PAHs

and veterinary drugs, and PAHs and pesticides in livestock are not yet known. In the environment, PAHs can react with pollutants such as nitrogen oxides and chlorine, yielding nitro- and chlorinated PAHs, respectively. These compounds are more persistent than unsubstituted PAH congeners and are likely to contaminate pastures and soil. Due to various interactions such as additivity, synergism, antagonism, and inhibition that occur in real-world chemical mixtures, information on the carryover will be of use in undertaking risk management practices.

## ACKNOWLEDGMENTS

# Brominated flame retardants and perfluorinated chemicals

Prasada Rao S. Kodavanti and Bommanna G. Loganathan

## INTRODUCTION

During the past several decades, concern has been raised regarding exposure and harmful health effects of synthetic organohalogen compounds, especially chlorine-containing compounds such as chlorinated pesticides and polychlorinated biphenyls (PCBs) in domestic animals, wildlife, and humans (Kodavanti *et al.*, 2008; Loganathan and Masunaga, 2008). There is mounting evidence that bromine- and fluorine-containing organohalogens are emerging as new pollutants that pose a threat on the global scale for present and future adverse health effects in animals and humans (Shaw and Kannan, 2009; Shaw *et al.*, 2010; Tanabe and Minh, 2010). Polybrominated diphenyl ethers (PBDEs) constitute an important group of chemicals of brominated flame retardants (BFRs) predominantly used in numerous industrial and consumer products to make these materials more fire resistant (Alaee *et al.*, 2003; Blum, 2010). The general chemical formula for PBDEs is  $C_{12}H_{10-x}Br_xO$ , and molecular weight ranges from 233 to 943. Perfluorinated compounds (PFCs) such as perfluorooctane sulfonate/sulfonic acid (PFOS) and related compounds are used as surfactants and have a wide range of industrial and commercial applications. The chemical formula for PFOS is  $C_8HF_{17}O_3S$ , and its molecular weight is 500. The structures of selected PBDEs and PFCs are shown in Figures 64.1–64.3. Unlike chlorinated compounds such as DDT (1,1,1-trichloro-2,2-bis[*p*-chlorophenyl]-ethane) and other pesticides (hexachlorobenzene, hexachlorocyclohexanes, etc.) that are used as agricultural/public health

insecticides, use of BFRs and/or PFCs has never resulted in direct exposure to farm and/or domestic animals and pet animals. However, due to their unique physicochemical and biochemical properties, both BFRs and PFCs persist and pervade every component of the global ecosystem, leading to exposure to animals and humans and contributing to negative health effects (Blum, 2010; Loganathan, 2011). The Stockholm Convention on persistent organic pollutants (POPs) included some of the PBDEs and PFCs in the POPs list (Stockholm Convention Secretariat, 2010). Although the production and use of PBDEs and PFCs are restricted, environmental contamination and harmful effects to animals and humans continue. In this chapter, the historical background of BFRs and PFCs, physicochemical properties, exposure, pharmacokinetics, mechanism of action, and effects are discussed with emphasis on domestic and pet animals.

## BACKGROUND

The first incidence of accidental poisoning caused by brominated compounds occurred in the early 1970s. Inadvertent use of polybrominated biphenyls (PBBs sold under the trade name FireMaster) in place of a cattle feed supplement, magnesium oxide (sold under the trade name NutriMaster), in the production of feed for dairy cattle resulted in the destruction of approximately 1.5 million chickens, 5 million eggs, 29,800 cattle, 34,000 pounds of milk products, 5920 hogs, and 1470 sheep on

**FIGURE 64.1** Chemical structures of brominated flame retardants. Structural similarities between polybrominated diphenyl ethers (PBDEs), polychlorinated biphenyls (PCBs), and polybrominated biphenyls (PBBs) are shown that are relevant to their mode of action. The letters “o,” “m,” and “p” respectively indicate *ortho*, *meta*, and *para* substitutions for chlorines or bromines. The numbers indicate the positions of halogens.

**FIGURE 64.2** Chemical structures of predominant PBDEs found in commercial mixtures as well as biological and environmental samples.

Michigan farms. The cost of this damage was approximately \$75–\$100 million (Carter, 1976; Fries, 1985). After this incidental poisoning via cattle feed, PBBs (Figure 64.1) were removed from the market. Of the brominated compounds still on the market, brominated bisphenols,

#### Chemical Structures of Selected Perfluorinated Compounds

**FIGURE 64.3** Chemical structures of predominant perfluorinated chemicals, PFOS (perfluorooctane sulfonic acid) and PFOA (perfluorooctanoic acid). The metabolites perfluorooctylsulfonamide and heptadecafluoro-1-decanol are shown for structural comparison.

diphenyl ethers, and cyclododecanes are three major classes that are still produced in large volumes (Shaw and Kannan, 2009). It is estimated that more than 1 million metric tons of PBDEs have been produced. Although the manufacture of penta- and octa-bromo mixtures has ceased, the production of decabromodiphenyl ether (decaBDE) continues in some countries (Guo *et al.*, 2011). DecaBDE was banned in Sweden and followed by partial bans in four U.S. states (Washington, Maine, Oregon, and Vermont) in 2007, the European Union in 2008, and Canada in 2009. The REACH (Registration, Evaluation, Authorization, and Restriction of Chemical Substances) program in the European Union announced in February 2011 the ban of hexabromocyclododecane (HBCD) used with all polystyrene in building insulation ([http://ec.europa.eu/environment/chemicals/reach/reach\\_intro.htm](http://ec.europa.eu/environment/chemicals/reach/reach_intro.htm)). In general, PBDEs and other brominated and chlorinated flame retardants in use are HBCD, decabromodiphenyl ether, tetrabromobisphenol-A (TBBPA), tris(1-chloro-2-propyl)phosphate,

tris(2-chloroethyl)phosphate, and Dechlorane Plus. These compounds are used in furniture, textiles, polyurethane foam, plastics used in electric and electronic equipment, printed circuit boards, curtains, carpets, etc. to meet fire safety standards (Alaee *et al.*, 2003; Stapleton *et al.*, 2009; De Wit *et al.*, 2010; Guo *et al.*, 2011). The high production volume and the structural similarities of these brominated chemicals to other well-known toxic environmental contaminants such as DDTs and PCBs are the main concerns for environmental and human/animal health. Furthermore, polybrominated dioxins (PBDDs)/dibenzofurans (PBDFs), formed during heating or incineration of BFRs, have toxicological profiles similar to those of their chlorinated homologs (Birnbaum *et al.*, 2003; DiGangi *et al.*, 2010), but they are more toxic than PBDEs. Like other organohalogenes, BFRs are ubiquitous in the environment, bioaccumulate, and are toxic to animals and humans (Dye *et al.*, 2007; Kodavanti *et al.*, 2008; Kierkegaard *et al.*, 2009; Ounnas *et al.*, 2010; Shaw *et al.*, 2010; Guo *et al.*, 2011).

PFCs are another class of persistent organohalogenes. PFCs differ from brominated and chlorinated organohalogenes by virtue of all hydrogen atoms, except those in the functional groups being substituted by fluorine atoms (Figure 64.3). PFCs have been used in a variety of specialized consumer and industrial products for more than 60 years. The applications of PFCs include heat-, chemical-, and abrasion-resistive coatings on utensils; they are also used as dispersion, wetting, or water protection for paper and surface treatments. In particular, PFCs are used in metal-plating baths, surfactants, cleaning products, rust inhibitors, fire-fighting applications, starting materials for polymers, herbicide and insecticide formulations, cosmetics, shampoos, pharmaceuticals, lubricants, paints, polishes, upholstery, textiles, carpets, soil/stain resistance coatings, mining and oil well surfactants, acid mist suppressants, electronic etching baths, alkaline cleaners, floor polishes, photographic film, and denture cleaners and adhesives (Senthilkumar, 2005; Kodavanti *et al.*, 2008; Yamashita *et al.*, 2011). PFCs are also used in paper protection, including food contact applications (plates, food containers, bags, and wraps) and non-food contact applications (folding cartons, carbonless forms, and masking papers) (Kannan *et al.*, 2002).

As a result of widespread use of these compounds, concern regarding PFC contamination has increased. PFOS and perfluorooctanoic acid (PFOA) have been consistently detected in environmental matrices, animals, and human tissues (Kannan *et al.*, 2004, 2005a,b). Although PFOCs have been produced since the late 1950s, these compounds were first reported to occur on a global scale in 2001 (Giesy and Kannan, 2001). Perfluorinated contaminants, such as perfluorobutanesulfonate, perfluorohexanesulfonate (PFHxS), perfluorononanoic acid (PFNA), perfluorodecanoic acid (PFDA), perfluoroundecanoic

acid (PFUnDA), perfluorododecanoic acid (PFDOA), and perfluorooctanesulfonamide (PFOSA), are less frequently detected in biota than are PFOS and PFOA. Studies suggest that PFCs accumulate in farm and pet animals such as chicken, cattle, goats, horses, pigs, and other vertebrates (Kennedy *et al.*, 2004; Guruge *et al.*, 2008).

## PHYSICOCHEMICAL PROPERTIES

### Brominated flame retardants

TBBPA (Figure 64.1), the highest volume flame retardant worldwide, is primarily a reactive BFR (90%) covalently bound to the polymer structure and less likely to be released into the environment than are additive flame retardants (Birnbaum and Bergman, 2010). TBBPA is used in several types of circuit board polymers. TBBPA is highly lipophilic ( $\log K_{ow} = 4.5$ ) and has low water solubility (0.72 mg/mL). TBBPA has been measured in the air (Zweidinger *et al.*, 1979), soil, and sediment (Watanabe *et al.*, 1983), but it is generally not found in water samples. TBBPA is found in eggs of birds, human milk, and umbilical cord serum. TBBPA derivatives such as ethers are reported to be biologically active, which may lead to health effects (Legler, 2008; Birnbaum and Bergman, 2010). HBCD (Figure 64.1) is a nonaromatic brominated cyclic alkane with a molecular weight of 641.7, and it is mainly used as an additive flame retardant in thermoplastic polymers with final applications in styrene resins (National Research Council, 2000). Like other BFRs, HBCD is highly lipophilic, with a  $\log K_{ow}$  of 5.6, and it has low water solubility (0.0034 mg/L) (MacGregor and Nixon, 1997). The melting point is 185–195°C, and vapor pressure is  $4.7 \times 10^{-7}$  mmHg. Studies have shown that HBCD is highly persistent, with a half-life of 3 days in air and 2025 days in water (Lyman, 1990), and it is bioaccumulative, with a bioconcentration factor of approximately 18,100 in fathead minnows (Veith and Defoe, 1979).

PBDEs are composed of two phenyl rings linked by an oxygen (thus the designation as “ether”; Figures 64.1 and 64.2). The phenyl rings may have 1–10 bromine atoms, leading to the formation of 209 possible congeners. The exact identity and pattern of various congeners in various commercial mixtures depend on the manufacturer and the specific product. Among these, the commercial “penta” mixture generally consists of PBDE congeners 99 (pentaBDE) and 47 (tetraBDE) as the major constituents (Figure 64.2), which comprise approximately 70% of the mixture (Huber and Ballschmiter, 2001). PBDE congener 100 (pentaBDE) is present at less than 10%, with PBDE congeners 153 and 154 (hexaBDEs) at less than 5% each. The commercial “octa” mixture is 10–12% hexaBDE, 43–44% heptaBDE, 31–35% octaBDE, 9–11%

nonaBDE, and 0–1% decaBDE. The “deca” commercial mixture consists of 98% decaBDE, with a small percentage of nonaBDEs (World Health Organization, 1994; LaGuardia *et al.*, 2006).

PBDEs are structurally similar to PCBs (Figure 64.1) and elicit adverse effects similar to those of PCBs on nervous, immune, and endocrine systems. They also influence metabolism of chemicals endogenous to the body as well as that of foreign chemicals. Compared to chlorine atoms, bromine atoms are in general lost more easily from the molecule (more “reactive”), rendering PBDEs more susceptible to various types of degradation and metabolism than PCBs (Table 64.1). Trace analysis of these commercial mixtures for other brominated contaminants revealed the presence of PBBs and PBDFs, but not PBDDs, at levels above the limit of detection (Hanari *et al.*, 2006). It is known that PBDEs, upon pyrolysis at 900°C, release

PBDFs and PBDDs, and the amount of these contaminants depends on the conditions of pyrolysis (Buser, 1986; Thoma *et al.*, 1986; Shaw *et al.*, 2010).

## Perfluorinated compounds

Perfluorinated compounds have ionic and neutral characters. Because of their thermodynamically strong covalent carbon–fluorine bonds, these compounds were initially considered as nontoxic and nonmetabolizable. It is apparent that carbon–fluorine bond has maximum energy compared to other bonds. Most of them were also considered to have little volatility. PFCs with considerable volatility are fluorotelomer alcohols (FTOHs or hydroxylated PFCs), which together with some sulfonamide-based PFCs may undergo transformation in the environment to form more persistent PFOA or similar perfluoroalkyl carboxylic or sulfonic acids. PFCs are water soluble in the several parts per million range (Table 64.2). PFCs with unique surface modification properties readily bind to surfaces including blood globulins (Kodavanti *et al.*, 2008).

The stability of the carbon–fluorine bond contributes to the persistence of PFCs in the environment and their ability to bioaccumulate and biomagnify in higher trophic levels of a food chain. PFOS has been shown to bioconcentrate from water into benthic invertebrates by three orders of magnitude and to bioaccumulate in top predators by 5- to 20-fold (Kannan *et al.*, 2005a). PFCs are also detected in wildlife and human tissues. Bald eagles, river otters, and bottlenose dolphins accumulate PFOS in their livers at microgram per gram tissue concentrations

TABLE 64.1 Physical and chemical properties of polybrominated diphenyl ethers

Property	PBDEs (penta-, octa-, and deca-BDE)
Physical state at room temperature	Pale yellow liquid to white powder
Molecular weight	564–959.2
Water solubility (µg/L at 25°C)	1
Boiling point (°C)	< 300 to >400
Melting point (°C)	85–306
Vapor pressure at 25°C (mmHg)	$2.2 \times 10^{-7}$ to $9 \times 10^{-10}$
Log $K_{ow}$	5.7–8.27
Henry's law constant (atm m <sup>3</sup> /mol)	$7.5 \times 10^{-8}$ to $1.2 \times 10^{-5}$

Data from ATSDR (2004) and De Wit (2002).

TABLE 64.2 Physical and chemical properties of perfluorinated compounds

Compound	Boiling point (°C)	Melting point (°C)	Vapor pressure at 20°C (Pa)	Water solubility (mg/L)	pK <sub>a</sub>	Henry's law constant (atm m <sup>3</sup> mol <sup>-1</sup> )
Perfluorooctane sulfonyl fluoride (POSF)	154–155		221			
Perfluorooctane sulfonic acid (PFOS)	149	70–100				
Perfluorooctane sulfonate potassium salt (PFOS K)		<400	$3.31 \times 10^{-4}$	570		$7.2 \times 10^{-9}$
N-ethyl-perfluorooctanesulfonamide (N-EtFOSA)	~110	~90	0.16			
Perfluorobutanoic acid (PFBA)	120	–19.5	1333			
Perfluoropentanoic acid (PFPeA)	127

Perfluoroheptanoic acid (PFHpA)	175–177					
Perfluorooctanoic acid (PFOA)	189–192	55	100	3400	2.5	$4.6 \times 10^{-6}$
Perfluorononanoic acid (PFNA)		71–77				
Perfluorodecanoic acid (PFDA)	218	83–85				
Perfluoroundecanoic acid (PFUnDA)	160	96–101				
Perfluorododecanoic acid (PFDoDA)	245	107–109				
8:2 fluorotelomer alcohol (8:2 FTOH)	95–105	42–44	356 at 25°C	0.14		$9.6 \times 10^{-2}$

Data from U.S. EPA (2000), Giesy and Kannan (2001), and Yamashita *et al.* (2011).

(Senthilkumar, 2005; Houde *et al.*, 2006). Furthermore, fluorinated acids are even found in ocean waters, Arctic ice, and Antarctic environment and biota (Yamashita *et al.*, 2011). Physical and chemical properties of PFCs are summarized in Table 64.2. PFCs are ubiquitous in the environment and bioaccumulate in animals and humans; their toxic properties are being revealed (Gill *et al.*, 2004).

## PHARMACOKINETICS AND TOXICOKINETICS

### Brominated flame retardants

The major pathway of TBBPA exposure is through diet, despite its low levels in the average diet in the United States. The bioavailability of TBBPA in circulation is very low even after administration of a high dose to rats due to rapid metabolism, indicating its low potential to bioaccumulate and cause toxic effects (Shaw *et al.*, 2010). TBBPA or its metabolites such as TBBPA-glucuronide, a diglucuronide, and a mixed glucuronide-sulfate were detected in bile and were excreted predominantly in feces; however, metabolites were also found in urine (Hakk *et al.*, 2000). After intravenous injection into rats, TBBPA was also rapidly cleared, and the majority of the intravenous dose was also recovered in the feces (Kuester *et al.*, 2007). Kinetic studies in rodents and humans suggest low absorption of TBBPA from the gastrointestinal tract and rapid metabolism of the absorbed TBBPA by conjugation (Schauer *et al.*, 2006; Kuester *et al.*, 2007).

Information on the toxicokinetics of HBCD is limited. HBCD is absorbed from the gastrointestinal tract, and major sources of human exposure are food and dust intake. There are three main diastereoisomers in the commercial HBCD mixture, denoted as  $\alpha$ ,  $\beta$ , and  $\gamma$ , with the  $\gamma$ -diastereoisomer predominating (>70%) (Heeb *et al.*, 2005). High levels of HBCD in some top predators indicate the persistence and biomagnification of HBCD. However, most early studies did not examine individual HBCD diastereoisomers but only the commercial HBCD mixture. Recent studies have shown that there is a predominance of the most persistent stereoisomer,  $\alpha$ -HBCD, in biota (Covaci *et al.*, 2006; Law *et al.*, 2006) and that individual diastereoisomers have different physical and chemical properties. There is a growing need to understand the individual diastereoisomers that make up the commercial mixture.

There are significant differences in the pharmacokinetic behavior of individual PBDE congeners and mixtures. These differences in absorption, distribution, metabolism, and excretion depend on the test animal species and the degree of bromination. As the number of bromine atoms increases from 4 to 10 bromines (tetraBDE to decaBDE), there are decreases in oral absorption, which leads to

shortened half-lives and increased elimination in both urine and feces. DecaBDE is poorly absorbed, with greater than 90% of the dose excreted in feces within 48 h (Morck *et al.*, 2003). Workers occupationally exposed to decaBDEs have shown decaBDE half-lives of approximately 15 days (Thuresson *et al.*, 2006), which is considerably shorter than those of other lower brominated congeners. DecaBDE has been found in the blood and breast milk of humans in the general population, but at lower levels than other PBDE congeners (Lorber, 2008).

Lower brominated PBDEs, in contrast to decaBDE, are more readily absorbed and persist in the body for many years because they are mainly stored in body fat. PBDE-47 and PBDE-99 are well absorbed and highly distributed to lipophilic tissues, such as adipose, skin, and liver tissue (Hakk *et al.*, 2002; Staskal *et al.*, 2005). In rats, tetra- and pentaBDEs are metabolized and eliminated slowly (Hakk *et al.*, 2002), whereas in mice, PBDE-47 is well absorbed and distributed, but its elimination is also rapid (Staskal *et al.*, 2005). Uptake efficiencies of BDE-47, BDE-99, and BDE-153 by pike fed trout injected with the congeners were 90, 62, and 40%, respectively (Bureau *et al.*, 1997).

### Perfluorinated compounds

Very limited information is available on the pharmacokinetics and toxicokinetics of perfluorochemicals in farm or domestic animals. Laboratory animal studies have shown that PFOS and PFOA are well absorbed orally, not metabolized, and poorly eliminated (Ophaug and Singer, 1980; DuPont Company, 1982; Johnson *et al.*, 1984; Vanden Heuvel *et al.*, 1991; Guruge *et al.*, 2006). Upon ingestion, these compounds are distributed primarily to the liver, kidney, and serum, with liver concentrations being the highest (Seacat *et al.*, 2002, 2003; Hundley *et al.*, 2006). PFOS and PFOA tend to bind to  $\beta$ -lipoproteins (Jones *et al.*, 2003), albumin, and liver fatty acid binding protein (Luebker *et al.*, 2002). Elimination rates and half-lives of PFCs vary with carbon chain length and animal species and gender tested. Hanhijarvi *et al.* (1988) reported that male hamsters excrete PFOA more rapidly than do females. In dogs, the half-life of PFOA is 20–30 days in males and 8–13 days in female. However, gender differences are not discernible in mice or rabbits (Hundley *et al.*, 2006; Lau *et al.*, 2006). The cause for gender and species differences in elimination of PFCs is not elucidated. Buist and Klaassen (2004) attributed these differences to the functions of organic anion transporters in the kidney because several transporter proteins are expressed differentially in male and female adult rats. Due to gender and species differences in elimination of PFCs, careful consideration must be given to compare toxicological effects. Further studies with emphasis on body burden rather than administered dose are warranted.

## MECHANISM OF ACTION AND TOXICITY

### Brominated flame retardants

TBBPA is of high ecotoxicologic concern due to its acute and chronic toxicity in several biota (U.S. EPA, 2008). TBBPA has been shown to be rapidly metabolized by mammalian livers and eliminated in bile, urine, and feces (Schauer *et al.*, 2006). TBBPA has been detected in various environmental media and biota, including air, soil, water, sediment, and bird muscle from electronic waste processing regions of China (Shi *et al.*, 2009), and also in bottlenose dolphins and bull sharks from the Florida coast (Johnson-Restrepo *et al.*, 2008). Currently, no restrictions are placed on the production and use of TBBPA. TBBPA is a cytotoxicant, immunotoxicant, and thyroid hormone (TH) agonist, and it has the potential to disrupt estrogen signaling (Birnbaum and Staskal, 2004). TBBPA is also toxic in rat brain cells *in vitro*, where it causes oxidative stress, calcium influx, and inhibits dopamine uptake (Reistad *et al.*, 2007). *In vivo* studies indicate that neonatal TBBPA exposure causes hearing deficits in rat offspring, similar to those observed following developmental exposure to PCBs (Lilienthal *et al.*, 2008). Nakajima *et al.* (2009) reported the presence of TBBPA in brain along with behavioral alterations following acute treatment of TBBPA. Disruption of TH homeostasis is proposed to be the primary toxic effect of TBBPA and other BFRs. TBBPA has a closer structural relation to thyroxine ( $T_4$ ) than to PCBs and binds to transthyretin (TTR) with greater affinity than it does to  $T_4$  (Meerts *et al.*, 2000). The detailed mechanism by which BFRs can disrupt TH homeostasis is discussed later (Figure 64.4).

Experimental studies showed that HBCD, the second most used flame retardant, has negative effects on endocrine and reproductive processes (Birnbaum and Staskal, 2004). Many effects of HBCDs seem to occur during development. During developmental exposure, HBCDs have been shown to decrease bone density and retinoids and to enhance immune response to sheep red blood cells (van der Ven *et al.*, 2009). HBCD isomers are endocrine disruptors with anti-androgenic properties that inhibit aromatase and interact with steroid hormone receptors (Hamers *et al.*, 2006). Like other BFRs, HBCDs may disrupt TH homeostasis, resulting in decreased  $T_4$  levels and increased thyroid-stimulating hormone (TSH) (Ema *et al.*, 2007). Studies indicate that a low dose of HBCD can potentially disrupt TH hormone receptor-mediated transactivation and impairs cerebellar Purkinje cell dendritogenesis (Ibhazehiebo *et al.*, 2011). The detailed mechanism by which BFRs can disrupt TH homeostasis is discussed later (Figure 64.4).

PBDE residues have been detected in indoor air, house dust, and foods (Schechter *et al.*, 2006; Sjodin *et al.*, 2008).

Sewage treatment plant effluents and biosolids are considered a major source of PBDEs (Rieck, 2004). More than half of the sewage sludge produced annually in the United States is applied to land as fertilizer (U.S. EPA, 1999). Agricultural land that has been treated with sewage sludge can be highly contaminated with PBDEs. Thus, application of sewage sludge may represent a source of exposure by direct contact or uptake through plants. In grazing animals including cattle, soil ingestion leads to contamination of meat and dairy products. In dairy cattle, the major intake of organohalogenes occurs via spontaneous soil ingestion during grazing (Fries, 1995). Cows ingest up to 1000g of soil per day (i.e., several micrograms of halogenated compounds daily) depending on several factors, including season, climate, and density of grass (Laurent *et al.*, 2005).

There are a few reports indicating high levels of serum PBDEs in household cats because of their high exposure to house dust (Dye *et al.*, 2007). In captive giant and red pandas, the tissue levels of PBDEs ranged from 38 to 2158ng/g lipid weight (lw) (Hu *et al.*, 2008). Kierkegaard *et al.* (2009) reported PBDE levels in cow milk (1100–2600pg/g lw) and fat (1300–2600pg/g lw). In Arctic fox, the levels of PBDEs are very low, ranging from 26 to 31ng/g lw (De Wit *et al.*, 2010). Whereas the levels of PBDEs in the liver of California sea otter are 2423ng/g lw (Kannan *et al.*, 2008), the levels are much higher in blubber of California sea lions, ranging from 569 to 24343ng/g lw (Stapleton *et al.*, 2006). In adipose tissue of polar bears in Canada, Muir *et al.* (2006) reported levels of PBDEs ranging from 4.6 to 11ng/g lw, and these levels were lower than those reported from polar bear fat samples from Svalbard and East Greenland. PBDE levels in domestic, pet, and wild animals are presented in Table 64.3.

Exposure to PBDEs in domestic/pet animals and humans may occur via multiple sources (air, water, dust, and food). Levels of PBDEs in animal and human tissues have increased exponentially since the 1970s in several countries, including the United States, Canada, and Sweden (Schechter *et al.*, 2005; Guo *et al.*, 2011). Elevated levels of PBDEs in North America have been attributed to the greater use of the pentaBDE mixture compared to its use throughout the rest of the world. Like other lipophilic compounds, PBDEs readily cross the placenta into the fetus, providing an opportunity for PBDEs to interfere with human and animal developmental processes.

Because PBDEs are predominantly used indoors, data on their effects on wildlife and farm animals are limited. A few studies indicate that PBDE exposure at environmentally relevant concentrations increases nestling growth (Fernie *et al.*, 2006) and causes changes in reproductive courtship behaviors in adult American kestrels (Fernie *et al.*, 2008). However, a number of studies

## Possible Mode(s) of Action for Thyroid Hormone Disruption

**FIGURE 64.4** Possible mechanisms by which BFRs can disrupt thyroid hormone (TH) homeostasis. PBDE is shown as an example of all BFRs. (1) BFRs as well as their contaminants enter the circulation from the gastrointestinal (GI) tract. (2) BFRs (parent compound as well as metabolites) can displace thyroxine (T4) from serum binding proteins such as transthyretin (TTR). The resulting free T4 will be subjected to hepatic metabolism and elimination. (3) Reduced circulating T4 levels trigger the hypothalamic-pituitary axis to synthesize and secrete more T4 by thyroid. (4) BFRs bound to TTR along with T4 will reach target organs including brain, where they can bind to TH receptor to elicit a biological/toxicological response. (5) After entering liver activate nuclear receptors, BFRs initiate transcription of xenobiotic-metabolizing enzymes for T4 metabolism and elimination. (6) Influx transporters further increase the T4 uptake and metabolism. (7) Efflux transporters eliminate T4 or its conjugates from liver into either serum or the bile. Figure is not to scale. Adapted from Kodavanti and Curras-Collazo (2010).

on laboratory animals have indicated that commercial PBDE mixtures as well as the individual PBDE congeners that compose them affect the nervous, endocrine, reproductive, and immune systems. With regard to neurotoxic effects, several studies have indicated that HBCD and PBDEs cause permanent aberrations in spontaneous behavior and habituation capability in mice after a single exposure at postnatal day (PND) 10 (a period of rapid brain growth development). It is interesting to note that the effects seen on this behavioral paradigm with PBDEs are identical to those produced by PCBs (Eriksson and

Fredriksson, 1996). Mice exposed to a single dose of PBDE 47 on PND 10 demonstrated delayed ontogeny of neuromotor function and hyperactivity when they attained adult age without any alterations in circulating TH levels (Gee and Moser, 2008; Gee *et al.*, 2008). Other studies showed developmental delays in the acquisition of the palpebral reflex following neonatal exposure to PBDE 209 along with changes in circulating T<sub>4</sub> levels (Rice *et al.*, 2007). Because of these differential reports, the role of hypothyroxinemia with regard to the behavioral effects of PBDEs is unclear. However, the mechanisms

TABLE 64.3 Polybrominated diphenylether levels in domestic, pet, and wild animals

Animal	Sample	Total PBDE concentration	Unit	Age (years)	Reference
Household cat <sup>a</sup>	Serum	4.3 ± 1.5 (3.5)	ng/MI	1.25–5	Dye <i>et al.</i> (2007)
	Serum	10.5 ± 3.5 (5.9)	ng/mL	8–15	Dye <i>et al.</i> (2007)
	Serum	12.7 ± 3.9 (6.2)	ng/mL	10–18	Dye <i>et al.</i> (2007)
Captive giant and red panda	Tissue	38.4–2,158	ng/g lw	NA	Hu <i>et al.</i> (2008)
Cow	Fat tissue	1,300–2,700	pg/g lw	NA	Kierkegaard <i>et al.</i> (2009)
Cow	Milk	1,100–2,600	pg/g lw	NA	Kierkegaard <i>et al.</i> (2009)
Moose	Liver	0.24–26 (BDE-47)	ng/g lw		De Wit <i>et al.</i> (2010)
		0.26–34 (BDE-99)			
Arctic fox	Subcutaneous adipose tissue	26.3	ng/g lw	NA	De Wit <i>et al.</i> (2010)
	Abdominal adipose tissue	31.6	ng/g lw	NA	De Wit <i>et al.</i> (2010)
	Blubber	569–24,343	ng/g lw	NA	Stapleton <i>et al.</i> (2006)
Polar bear	Adipose tissue	4.6–11	ng/g lw		Muir <i>et al.</i> (2006)
California sea otter	Liver	2,423 ( <i>n</i> = 6)	ng/g lw		Kannan <i>et al.</i> (2008)
Silver perch	Whole fish	337 ( <i>n</i> = 2)	ng/g lw		Sajwan <i>et al.</i> (2008)

<sup>a</sup>Total PBDE concentrations in parentheses indicate median.

NA, not available.

by which PBDEs or other BFRs disrupt TH homeostasis are shown in Figure 64.4. BFRs as well as their contaminants enter the circulatory system from the gastrointestinal tract. T<sub>4</sub> is synthesized and released into circulation by the thyroid gland. In circulation, BFRs (parent compound as well as metabolites) can displace T<sub>4</sub> from serum binding proteins such as TTR. The resulting free T<sub>4</sub> will be subjected to hepatic metabolism and elimination. The reductions in circulating T<sub>4</sub> levels increase TSH production via reduced negative feedback on the hypothalamic–pituitary axis, which induces increased synthesis and secretion of T<sub>4</sub> by the thyroid gland. BFRs bound to TTR along with T<sub>4</sub> will reach target organs including the brain, in which they can bind to the TH receptor to elicit a biological/toxicological response. In the liver, BFRs activate nuclear receptors, initiating transcription of xenobiotic metabolizing enzymes for T<sub>4</sub> metabolism and elimination. Influx transporters further increase the T<sub>4</sub> uptake and metabolism, whereas efflux transporters eliminate T<sub>4</sub> or its conjugates from the liver into either serum or the bile (Figure 64.4). Given the key role of TH in development, BFR-induced perturbations in TH homeostasis might play a role in the outcome of adverse effects associated with BFR exposure.

Studies indicate that a commercial pentabrominated mixture (DE-71), when administered during development, did not alter maternal or male offspring body weights. However, female offspring were smaller compared to controls from PND 35 to 60. DE-71 exposure also accumulated PBDE congeners in various tissues including brain, suggesting that PBDEs cross the blood–placenta and blood–brain barriers, causing subtle changes in some parameters of neurobehavior and

dramatic changes in circulating thyroid hormone levels, as well as changes in both male and female reproductive end points (Kodavanti *et al.*, 2010).

In addition to the effects on TH, there is evidence that PBDEs affect the cholinergic neurotransmitter system (Viberg *et al.*, 2003a,b), which is involved in memory and motor function, among others. Several PBDE congeners have been compared to PCBs with regard to their ability to affect intracellular signaling in a cerebellar (brain) culture system (Kodavanti and Ward, 2005; Kodavanti *et al.*, 2005; Fan *et al.*, 2010). The Ca/protein kinase C signaling pathways are also proposed as mechanisms of neurotoxicity for a number of chemicals, including PCBs and PBDEs. The order of potency for their effects on intracellular signaling was DE-71 (a commercial mixture of tetra-, penta-, and hexaBDEs) > 47 > 100 > 99. On a molar basis, DE-71 was equipotent with Aroclor 1254; the most widely used commercial PCB mixture. A Swedish study found that PBDE-99 and PCB-52 produced effects on behavior when given together but not at the same dose given alone (Eriksson *et al.*, 2006). These results suggest that there may be little difference in neurotoxic potency between PBDEs and PCBs, and that effects of PCBs and PBDEs are additive. This implies that body burdens of PCBs and PBDEs in humans may need to be added when assessing risk.

## Perfluorinated compounds

Table 64.4 summarizes PFC concentrations in farm and pet/captive animals. Detectable levels of PFCs were found in serum samples from chicken, pigs, cattle (Jack Black),

TABLE 64.4 Perfluorinated compound concentrations in farm and pet/captive animals

Species	N	Location	PFC concentrations (ng/mL wet wt.)					Reference
			PFOS	PFHxS	PFDA	PFNA	PFOA	
Chicken/serum	7	Japan	4.9	0.07	0.06	0.22	0.44	Guruge <i>et al.</i> (2008)
Pig/serum	6	Japan	0.57	0.04	0.07	0.12	0.23	Guruge <i>et al.</i> (2008)
Cattle, Jack Black/serum	5	Japan	1.5	0.01	0.48	0.04	0.01	Guruge <i>et al.</i> (2008)
Horse/serum	2	Japan	0.82	<0.01	0.5	0.04	<0.05	Guruge <i>et al.</i> (2008)
Dog/serum	10	Japan	25	10	0.28	1.5	2.5	Guruge <i>et al.</i> (2008)
Goat/plasma	5	Japan	2.4	0.05	1.0	1.2	0.13	Guruge <i>et al.</i> (2008)
Amur tiger/serum	100	China	1.41	0.11	0.07	0.32	0.11	Li <i>et al.</i> (2008)
Polar bear/liver <sup>a</sup>	NR	Svalbard	1290	2940	43	102	21	Kannan <i>et al.</i> (2005b)

Red panda/serum	12	China	15.65	NA	NA	NA	2.29	Dai <i>et al.</i> (2006)
Bottlenose dolphin/serum	2	Bermuda	49	5.9	9.6	17	0.8	Giesy and Kannan (2001)

<sup>a</sup>Indicates levels found in liver compared to others reported in serum.

NA, not available.

horses, dogs, and goats from Japan (Guruge *et al.*, 2008). Among several PFCs measured, PFOS and PFOA concentrations were consistently higher in almost all samples. The serum PFOS and PFOA concentrations ranged from 0.57 to 4.9 ng/g wet weight and from less than 0.05 to 2.5 ng/g wet weight, respectively (Table 64.4). Serum samples of Amur tigers, giant pandas, and red pandas from China also contained detectable concentrations of PFCs (Dai *et al.*, 2006; Li *et al.*, 2008). As observed in farm animals, Amur tiger and panda serum samples had comparatively higher concentrations of PFOS than other PFCs, including PFOA. Animal tissue samples from remote locations, such as polar bear liver samples from Svalbard and serum samples from bottlenose dolphin from Bermuda, also showed relatively high concentrations of PFOS compared to other PFCs (Table 64.4). Polar bear liver contained 1290 ng/g wet weight of PFOS and 2940 ng/g wet weight of PFHxS (Kannan *et al.*, 2005b).

Perfluorochemicals, especially PFOS and PFOA, were associated with liver enlargement and hepatocellular adenomas in rats (Lau *et al.*, 2007). Lau and co-workers suggested that agonism of the peroxisome proliferator-activated receptor- $\alpha$  (PPAR- $\alpha$ ) may be involved in tumor (primarily liver) induction by a number of non-genotoxic carcinogens in the rodents. Following this, a number of studies were conducted to determine whether the PPAR- $\alpha$  agonistic mode of action is involved in the liver toxicity and hepatocellular adenomas observed in rats treated with PFOS and PFOA. Several short-term studies in rats and mice have revealed that PFOS and PFOA are capable of inducing peroxisome proliferation, and the first key event in this mode of action is activation of PPAR- $\alpha$  (Ikeda *et al.*, 1987; Berthiaume and Wallace, 2002; 3M Company, 2004; Vanden Huevel *et al.*, 2006). Because several PFCs can activate PPAR- $\alpha$ , these

compounds may also induce peroxisome proliferation by perturbing lipid metabolism and transport. Maloney and Waxman (1999) reported that PPAR- $\alpha$  was activated by endogenous cellular fatty acids. Based on these observations, Lau *et al.* (2007) suggested that displacement of endogenous ligands from L-FABP may be one of the mechanisms by which PFOS induces peroxisome proliferation. In addition, Yang *et al.* (2002a,b) showed that the activation of PPAR- $\alpha$  by PFOA was consistent with a significant increase in liver weight in wild-type mice exposed to dietary PFOA or WY-14,643, a classical peroxisome proliferator, at 0.02 and 0.125% (wt/wt), respectively, for 7 days.

Because PPAR- $\alpha$  controls lipid metabolism and transport, the hepatomegaly observed in PPAR- $\alpha$  in null mice was attributed to accumulation of lipid droplets or accumulation of PFOA in the liver (Yang *et al.*, 2006). Guruge *et al.* (2006) studied gene expression profiles in rat liver with PFOA and showed that the largest categories of induced genes are those participating in metabolism and transport of lipids (fatty acids). PFOA not only exhibits properties of a peroxisome proliferator but also possesses the properties of a mixed-type enzyme-inducing agent, as demonstrated by marked induction of CYP2B2, CYP3A4, and CYP4A1 in liver microsomes (Elcombe *et al.*, 2007). Kudo *et al.* (2000) studied the induction of peroxisomal  $\beta$ -oxidation by perfluorochemicals in rat livers by administration of PFCs at doses ranging from 2.5 to 20 mg/kg/day for 5 days and found that in male rats, all compounds except PFHA induced the activity of peroxisomal  $\beta$ -oxidation. However, in female rats, PFNA and PFDA induced the activity. Differences in accumulation of these compounds in the rat livers may be responsible for the different hepatic responses observed between various PFCs with different carbon chain length and between sexes.

In multicellular organisms, cells communicate (exchange ions, send messages, and exchange small molecules) by a process known as gap junctional intercellular communication (GJIC). GJIC maintains tissue homeostasis and is involved in growth, development, and differentiation (Lau *et al.*, 2007). Trosko and Rush (1998) suggested that loss of GJIC plays a role in carcinogenesis. Hu *et al.* (2002) showed that rats exposed orally (5 mg/kg) for 3 days or 3 weeks inhibit GJIC, and GJIC is also inhibited in a dose-dependent manner in rat liver and dolphin kidney cell lines. However, the pathophysiological significance of GJIC inhibition with regard to the carcinogenic mode of action for PFOS and PFOA is unclear.

It is important to mention that PBDEs, PFOS, and PFOA have strong potential for reproductive and developmental toxicity (Johansson *et al.*, 2009; Kodavanti *et al.*, 2011; Abdelouahab *et al.*, 2011).

## CONCLUSION AND FUTURE DIRECTIONS

Brominated flame retardants and perfluorinated compounds are considered emerging environmental pollutants. During the past few decades, there has been a great deal of progress in understanding the distribution of these pollutants in the global environment, wildlife, and humans. Although monitoring studies have clearly shown the presence of BFRs and PFCs worldwide, environmental/biological transformation and toxicology, pathways, and mode of action are not fully understood or described. Furthermore, contamination levels and potential negative effects of these toxic pollutants on domestic and pet animals have been largely ignored. Laboratory animal studies and accidental poisoning case studies have shown that exposure to BFRs and/or PFCs may result in serious health effects, including endocrine disruption leading to reproductive and immune dysfunction, birth defects, neurotoxicity, and certain types of cancers. Based on laboratory and field study results, environmental exposure of farm animals to BFRs and PFCs is of great concern because these compounds can affect animal health as well as serve as a source for human exposure via consumption of contaminated meat and/or dairy products. Although some BFRs have been banned or voluntarily withdrawn by manufacturers, human/animal exposure to these chemicals will continue for a long time, as is the case with chlorinated organic chemicals that exist in large quantities in consumer products (Shaw *et al.*, 2010). Therefore, research is needed to address the long-term consequences of exposure to these chemicals even as new brominated replacement chemicals enter into the market.

## ACKNOWLEDGMENTS

We thank Dr. Susan Shaw of Marine Environmental Research Institute (Blue Hill, ME), Dr. Ramesh Gupta of Murray State University (Hopkinsville, KY), and Dr. Shigeki Masunaga of Yokohama National University (Yokohama, Japan) for their excellent comments on an earlier version of this chapter. The contents of this article have been reviewed by the National Health and Environmental Effects Research Laboratory of the U.S. Environmental Protection Agency and approved for publication. Approval does not signify that the contents necessarily reflect the views and policies of the Agency, nor does mention of trade names or commercial products constitute endorsement or recommendation for use.

# Veterinary geology

Jan G. Myburgh

## INTRODUCTION

Links between the natural environment and human health have been recognized for centuries (Webb, 1964; Plant *et al.*, 1996; Skinner 2007). Ancient Chinese, Egyptian, Islamic, and Greek writings described many health problems. Hippocrates and Aristotle noted relationships between environmental factors and the distribution of various diseases (Bunnell, 2004). However, it is not only areas with excesses (toxicity) that are important; extensive regions have also been shown to have levels of essential inorganic elements well below (deficiency) what is needed (Plant *et al.*, 1996). The positive effects of a large number of different minerals that were used for medicinal purposes were already described more than 2000 years ago in Chinese texts, and these were used for their healing properties (Bunnell, 2004).

Similarly, environmental effects on animal and plant health are also well recognized (Underwood and Suttle, 1999; Whitehead, 2000; He *et al.*, 2005). Farm animals and wildlife are in general more directly dependent on their local environment for the supply of inorganic elements than are humans (Thornton, 2002, 2010; Steinnes, 2009). Animals are seldom moved around, except if they belong to nomadic farmers, and are constantly exposed to local environmental factors (geochemistry and water) if abnormal. Humans, on the other hand, usually buy vegetables and food at local markets that have come from other areas, even in developing countries, thereby effectively reducing the risk of being affected by local anomalies in the area (Mills, 1996; Plant *et al.*, 1996).

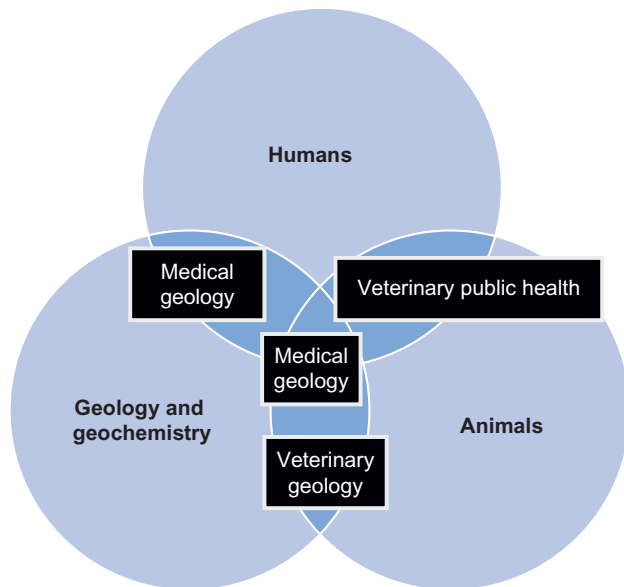

Because livestock and wildlife are closely associated with their environment, any geological anomaly (abnormality in soil chemistry and groundwater

composition) will be mirrored in their health (Edmunds and Smedley, 1996; Plant *et al.*, 1996; Thornton, 2002; Frank, 2004). Animals that are looked after intensively, such as dairy cows and feedlot animals, receive their feed from other areas and are unlikely to be affected by a local problem, except for abnormalities in groundwater (e.g., fluorosis). Wildlife migration probably reduces the risk of exposure to local geochemical anomalies (Thornton, 2002; Maskall and Thornton, 1996).

## MEDICAL GEOLOGY

Medical geology is a rapidly growing field concerned with the relationship between natural geological factors and human and animal health (Selinus *et al.*, 2005). To support this multidisciplinary field, the International Medical Geology Association ([www.medicalgeology.org](http://www.medicalgeology.org)) was formed, and a textbook (*Essentials of Medical Geology*) was published by prominent researchers in this field (Davies *et al.*, 2005). Several other textbooks and numerous publications have been published (Bowman *et al.*, 2003; Bunnell, 2004; Bunnell *et al.*, 2007; Skinner, 2007; Dissanayake and Chandrajith, 2009; Steinnes, 2009).

Medical geology is recognized as a subject discipline, and it is taught at several universities as a specific subject (Davies *et al.*, 2005). Although it refers to animal health, the focus is mainly on human health (Aggett and Mills, 1996; Davies, 2008; Lar and Tejan, 2008; Dissanayake and Chandrajith, 2009; Rapant *et al.*, 2009). It is important to realize that animal health also affects human health through animal products such as meat and milk.

**FIGURE 65.1** Schematic relationship between human health, animal health, and environment (geology and geochemistry). The interfaces – namely medical geology, veterinary geology, and veterinary public health – are also indicated.

## VETERINARY GEOLOGY

Although the term veterinary geology has not been used before, the focus is very similar to that of medical geology (Davies *et al.*, 2005; Jones, 2005). It is proposed that we use the term veterinary geology in specific cases to emphasize the importance of geology (geochemistry and groundwater) in animal health and where animals are specifically affected or studied (Figure 65.1).

If animals are affected by their environment, very often humans living in that specific area will also be affected (e.g., fluorosis). This is very often seen in rural villages, where humans and their animals are not moving around much and must use the same environment and water. Medical doctors or researchers who focus on human health usually underestimate farm animals as sentinels for environmental problems.

Veterinary geology focuses on the effects that geology and geochemistry have on the health, production, and reproduction of animals, including livestock, wildlife, and companion animals. The natural geologic environment as well as anthropogenic changes to the environment, such as mining or farming activities, should also be included. It is important to note that even drinking water may be influenced to a certain degree by the local geology (Edmunds and Smedley, 1996).

Farm animals, kept extensively or semi-extensively, and wildlife are closely associated with their natural environment. Nowadays, livestock are kept in smaller

areas due to space constraints. Geological anomalies may have a larger impact if animals are fenced in or “trapped” in these specific areas. This is more important in developing countries, where balanced rations and supplementary feeding are not as routinely used to improve the health of livestock.

In southern Africa, very expensive wildlife, such as roan, sable, and African buffalo, are also kept in small camps to prevent poaching and to facilitate constant observation. If these animals are trapped on geological anomalies, it will affect their health, especially if they are kept in one of these areas for long periods. Wildlife farmers very often believe that wildlife do not need special attention, as required by livestock; however, if they are fenced in, in a specific area, they need to be managed like farm animals. Farming with wildlife outside their normal distribution ranges has also caused problems due to animals not adapted to specific areas. Animals take in soil while grazing, and this may also influence their health in either positive or negative ways (Kreulen, 1985).

## PROBLEMS IN ANIMALS ASSOCIATED WITH GEOCHEMISTRY

Rural people have always recognized that the health of their animals is influenced by the animals’ diet and, therefore, soil properties. These observations could not be explained until the advent of scientific agriculture in the 19th century, when it required only a small step to suggest that humans may also be caught up in similar relationships. Diseases now known to be caused by a lack or excess of elements in the soil and plants were given names that reflected where they occurred, such as Derbyshire neck in the iodine-deficient areas of the English Midlands or Bodmin Moor sickness over the granites of southwest England, where cobalt deficiency is endemic in sheep unless treated. It is interesting to note that in Japan, before the 1868 Meiji Restoration, meat was rarely eaten so there was no tradition of animal husbandry. Japanese authors have suggested that this lack of animal indicators largely contributed to the failure to recognize the significance of metal pollution until it became catastrophic (Davies *et al.*, 2005).

It is important that veterinarians, animal scientists, and soil scientists take note of veterinary geology. Plants will also to some degree reflect what is in the environment. Geological anomalies may affect the health of animals through mineral imbalances (e.g., high molybdenum and copper deficiency), deficiencies (e.g., low cobalt in sandy soil), or intake of abnormally high concentrations of elements (e.g., selenium) (Frank, 2004; Plant *et al.*, 1996; Thornton, 2002; Underwood and Suttle, 1999).

Livestock and wildlife sometimes deliberately eat soil. However, the involuntary intake of soil through normal grazing probably influences the mineral status of animals more than does the deliberate eating of soil. Geophagia is well known but still not clearly understood (Kreulen, 1985).

In Southern Africa very expensive wildlife (roan, sable and buffalo) are often kept in smaller camps. If these animals are trapped in an area with a geological anomaly, their health will be affected.

During the purchase of a farm, it is imperative that a scientist examine the local geology and advise the prospective buyer about the environment. Migration of animals is not possible anymore in the modern farming community. Nomadic farming with cattle is disappearing, and the natural migration of wildlife is hampered by fences, highways, and private property. Animals moving into an area low seasonally could take in high concentrations of specific elements. However, very often they move out at the end of the season and are not clinically affected. Modern humans buy from local markets, thus avoiding problems because products are delivered from different areas (Maskall and Thornton, 1996; Thornton, 2002).

Mining has a major effect on animal health. Anthropogenic changes to the geological environment are also included in this definition. The veterinary public health issue must also not be ignored.

## PROBLEMS ASSOCIATED WITH WATER

Whoever wishes to investigate medicine properly, should proceed thus.... We must also consider the qualities of the waters, for as they differ from one another in taste and weight, so also do they differ much in their quality.

Hippocrates (460–377 BC)

The detrimental effects of poor quality drinking water are well known (Edmunds and Smedley, 1996; Dissanayake and Chandrajith, 2009). Poor quality water may cause acute deaths (e.g., nitrate poisoning) or chronic health effects (e.g., fluorosis) in farm animals. It is possible to delineate large areas containing element deficiencies that are closely related to the local geology and/or geographical location. Three elements (Se, Fe, and I) cause well-documented deficiency-related health problems, although Se and Fe also give rise to disease if presented above threshold values (Edmunds and Smedley, 1996).

Water, however, may be a useful indicator of local environmental levels of trace elements (e.g., in food, soil, rocks, and the atmosphere). The link between excesses or deficiencies of particular trace elements and the health of

humans and animals are likely to be more noticeable in developing countries, especially in rural areas, because of a much greater dependence on water and food of local provenance (Edmunds and Smedley, 1996; Fordyce *et al.*, 1996; Plant *et al.*, 1996).

## CONCLUSIONS

Because livestock and wildlife are closely associated with their environment, especially animals that are kept extensively, any geological anomaly (abnormality in soil chemistry and groundwater composition) will be mirrored in their health. Although the term veterinary geology has not been used before, it is very similar to medical geology, with a focus on animal health. The term veterinary geology is proposed to emphasize the importance of geology in animal health and to be used when referring to where animals are specifically affected or studied.

# Principles of ecotoxicology

Val R. Beasley and Jeffrey M. Levensgood

## INTRODUCTION AND CORE CONCEPTS

One Health is a term that is gaining ground because it recognizes the reality that the health of humans, domestic animals, wildlife, and ecosystems are inextricably interdependent. One Toxicology is a term reflecting similar interdependence in the study of chemically induced diseases and how human toxicology, domestic animal toxicology, wildlife toxicology, and ecotoxicology inform one another (Beasley, 2009). Also, poorer people and wildlife have much in common. They tend to be exposed to highly toxic chemicals in the environment more than their wealthier or domesticated counterparts. Poor people and wildlife also rely more on native species for food; therefore, protecting one group can often protect the other. This chapter provides information on select toxicants and issues of importance in ecotoxicology and environmental toxicology (i.e., the study of outdoor contaminants on human beings).

### Definitions

Hoffman *et al.* (2003) defined ecotoxicology as “the science of predicting effects of potentially toxic agents on natural ecosystems and on non-target species.” Newman (1998) offered a more expansive definition of ecotoxicology as the “science of contaminants in the biosphere and their effects on constituents of the biosphere,” but this could be taken to encompass all of toxicology. Of course, ecology is the science of the interactions among living organisms and the environment, and ecotoxicology includes not only predictions but also diagnoses,

management, and preventive actions. Although ecotoxicology draws on knowledge from all species, it focuses on free-ranging life-forms. We define toxicology as the science of the adverse biochemically mediated effects of all chemicals on all life-forms. Thus, we define ecotoxicology as the science of the adverse biochemically mediated effects of all chemicals and combinations of chemicals on all free-ranging organisms and on their interactions with one another and the environment. The breadth of ecotoxicology is apparent not only in these definitions but also through common types of research that it involves, which include studies of (1) the transport, fate, and concentrations of contaminants in the environment; (2) the fate of contaminants in native species; (3) the pathophysiologic effects of single chemicals on a single native or surrogate microbe, plant, or animal species in the laboratory; (4) the pathophysiologic effects of controlled amounts of single chemicals and groups of chemicals on suites of organisms in microcosms or mesocosms; and (5) the impacts of environmental contaminants on suites of biotic and abiotic components in field studies. Because of the permutations of organisms and exposures in the world today, ecotoxicology is clearly one of the most encompassing and challenging specialties under the larger umbrella of toxicology.

### Successes and challenges

The necessity of integrated field and laboratory research was illustrated in studies of dichlorodiphenyltrichloroethane (DDT) on avian reproduction. The insecticidal properties of DDT were discovered during World War II, and it was used to counter malaria and typhus in troops via control of mosquito and flea vectors,

respectively. Agricultural applications began after World War II. Large amounts were sprayed on farm fields in the United States, Great Britain, and elsewhere. According to the Agency for Toxic Substances and Disease Registry, DDT production peaked in 1962, when 85,000 tons were produced in the United States alone. An estimated 675,000 tons were applied in the United States during 1945–1972. Due to its low acute toxicity to most bird and mammal species, DDT was initially considered safe.

After noting increased raptor nests with broken eggs in the United Kingdom, Ratcliffe (1967) undertook research that revealed precipitous declines in ratios of shell weights to egg sizes in three species of birds from 1946 to 1950, after which the thinning persisted. Thickness of eggshells from 1947 to 1967 was significantly less than that from 1900 to 1946. Jefferies (1967) linked DDT to delayed ovulation in birds, suggesting endocrine disruption. This was followed by many corroborative field and laboratory studies that offered overwhelming evidence on the insidious, devastating impacts of DDT on avian reproduction. The effects of DDT on eggs were ultimately linked to its persistent metabolite, dichlorodiphenyldichloroethylene (*p,p'*-DDE), which inhibits prostaglandin synthetase and CarATPase, resulting in reduced calcium uptake by the shell gland mucosa during eggshell formation. Due to the thin eggshells, adult birds of many species crushed their eggs during incubation (Henny *et al.*, 1985; Burgers *et al.*, 1986; Newton *et al.*, 1989; Wiemeyer *et al.*, 1993; Bowerman *et al.*, 1995; Lundholm, 1997; Grasman *et al.*, 1998).

Pest resistance necessitating development of alternatives, decades of accumulated evidence on environmental impacts, and the publication of *Silent Spring* by Rachel Carson in 1962 prompted the ban on most uses of DDT by the U.S. Environmental Protection Agency (EPA) in June 1972. Many other developed nations banned DDT and pressured less affluent countries to discontinue or curtail its use. In 2005, however, the World Health Organization and the Stockholm Convention on Persistent Organic Pollutants condoned limited use of DDT for indoor mosquito control in tropical malaria-endemic areas.

Although DDE residues are declining, it is still widely disseminated in the environment. Also, an emerging concern regards freeing of organochlorines from melting ice caps. This phenomenon has been linked to elevated concentrations of parent DDT in Adelie penguins in the Antarctic (Geisz *et al.*, 2008).

Research and stewardship in ecotoxicology have (1) helped reduce dissemination of some major environmental pollutants (e.g., DDT, polychlorinated biphenyls (PCBs), and lead shot), (2) prompted development of chemicals of lower environmental risk (e.g., insect growth hormone mimics), (3) helped applied ecology to focus more on biochemical endpoints, (4) improved the effectiveness of ecological restorations in previously

contaminated habitats, and, thus, (5) increased the effectiveness of conservation medicine and ecosystem health professionals.

Despite the success stories of ecotoxicology, as well as conservation biology and ecosystem health, stewardship remains extremely uneven throughout the United States and the world. In many places, since the publication of *Silent Spring*, mismanagement of ecological resources has continued or even accelerated. The failure to protect groups of organisms that represent millions of years of coevolution is often related to powerful economic interests (e.g., mining, petroleum, energy generation, synthetic chemical, construction, and agricultural and forestry industries), poor people who are desperate for food and income, and short-sighted political pressure. The outcomes include tolerance of avoidable contamination that results in profound stress, impaired reproduction, and reduced survival in wild plants and animals. Of concern is that no new, major legislation in support of ecosystem health has been passed by the U.S. Congress since 1990. Increasingly, it is Europe, rather than the United States, that is becoming the proactive leader in regard to environmental contaminants.

Environmental pollutants of great importance in the 21st century include industrial chemicals, combustion products, pesticides, flame retardants, salts, acids, nutrients, and heavy metals. Combined with aggressive and careless actions that cause habitat loss, overharvest of native species, introductions of exotic species, climate change, and increasing exposures to pathogens, contaminants are contributing to an accelerating sixth extinction (Pimm *et al.*, 1995). Problems related to environmental contamination persist in much of the developed world, and they are burgeoning in areas of the developing world where mineral extraction, industrialization, and urbanization are proceeding at unprecedented rates and environmental monitoring and regulation are weak and often corrupt. The developed world increasingly relies on agricultural products, raw materials, and manufactured goods from the developing world. Unfortunately while developed world citizens may insist on ecological stewardship in their home countries, many remain oblivious to their roles as consumers whose purchases drive uncontrolled pollution of the developing world.

Problems are made worse by the limited involvement of veterinary toxicology in the generation of diagnostic criteria for use in ecotoxicology. Historically, few ecotoxicologists have linked exposures and residues in animals to clinical signs, clinical pathology changes, and lesions. Even now, regulatory criteria in ecotoxicology often fail to require characterization of residues and histopathologic lesions in test organisms. Thus, there is a need for more stringent regulations and, in the meantime, for more veterinary toxicologists and analytical toxicologists to take wildlife and ecological samples into the

laboratory for basic, applied, and forensic studies. Early diagnoses, source identification, pollution prevention, cleanups, and replacement of problem chemicals with less toxic alternatives can be the outcomes of applying the everyday approach of veterinary toxicologists to wildlife and ecosystems.

Improved stewardship of chemicals is a key component of reestablishing sustainability of life on Earth. Limiting the harm induced by chemical pollution should be the easy part of ecological stewardship, but those with the capacity to bring about improvements must find the resources and the will necessary to do a better job. The positive benefits of such actions include improved human economic well-being and less morbidity and mortality in wild species. Protection of ecosystems from the impacts of environmental contaminants can readily protect the lives of billions of wild plants and animals as well as the health of innumerable domestic animals and human beings. In addition to their roles as members of populations, biotic communities, and ecosystems, many wild species of shellfish, fish, birds, and mammals are economically important and extremely healthy sources of protein. However, for such species to serve as an efficient and safe source of food that can be shared by humans and predators of an array of other species, their populations must be sustainable and they must not present unwarranted chemical hazards. Major challenges are at hand, but the methods to improve conditions are known. The issue is whether they will be applied at local, national, international, and global scales to fuse and achieve economic, ethical, and ecological goals.

## Sources of pollution

Myriad toxic substances are released into our environment daily. Toxic agents are either deliberately manufactured (e.g., pesticides, drugs, construction chemicals, and household chemicals) or accidentally produced (e.g., byproducts in both final formulations and airborne, liquid, and solid waste streams). Inappropriate siting and operation of chemical manufacturing and waste storage facilities can lead to acute and chronic chemical contamination of groundwater, surface water, sediment, soil, air, and resident biota. Chemical and textile manufacturing plants, tanneries, refineries, smelters, chemical storage facilities, and electricity generating plants were often located near waterways for ease of transportation of raw materials and finished products, for access to large quantities of water used in manufacturing, and/or to allow for dissemination of wastes. Such siting predisposes to deliberate (sometimes permitted), accidental, and even malicious releases of toxic chemicals into aquatic ecosystems.

Environmental contamination can emanate from point sources such as industries, mines, refineries,

coal-burning power plants, or sewage treatment plants. Contaminants can also enter the environment from non-point sources, such as pesticides washed from large areas of land after precipitation, effluents from the tailpipes of myriad motor vehicles, or semivolatile pollutants that circle the globe after evaporation from the soils of agricultural and urban environments.

## Environmental fate and bioavailability of chemicals

Our environmental contamination problems are complex but controllable by limiting environmental pollution so that concentrations are not high enough to harm prokaryotic and eukaryotic life-forms beyond target sites, such as an agricultural field being treated because an arthropod pest is attacking a monoculture, thereby reducing the yield and quality of the harvest. Although the assimilative capacity of most natural environments is tremendous, responsible stewardship should always ensure that pollutants are not produced and used at rates that undermine the capacity of the environment for rapid detoxification.
